ABSTRACT

In this paper, we report the shape-controlled growth of MgH_2/Mg nano/microstructures via hydriding chemical vapor deposition (HCVD), wherein magnesium vapor was deposited on a substrate at different temperatures ranging from 225 °C to 600 °C and H_2 pressures ranging from 1 to 4 MPa. The products obtained after heating for 7, 13, and 20 h were identified by XRD and observed by SEM. The shape, size, and purity of the products strongly depended on the experimental conditions, which were classified according to the P-T equilibrium diagram for MgH_2 . The diagram showed six distinct areas for the products MgH_2 and/or Mg having the following structures: fine and coarse powder, dendrite, root-like structure, straight and curved fibers, irregular bulk structure, and hexagonal and spherical structures. The diagram can be used quite effectively for controlling the shape of MgH_2 and/or Mg, and this may lay the foundation for the mass production of nano/microsized MgH_2/Mg for use in hydrogen storage or batteries.

KEYWORDS Hydrogen storage, magnesium hydride, nanostructures, crystal growth, hydriding chemical vapor deposition

Introduction

Crystal growth of nano/micro materials has received increased attention because these materials exhibit unique properties and can be used in various applications.^{1,2} In this respect, the synthesis of Mg/MgH₂ nano/microstructures could be of interest in the field of hydrogen storage and batteries.³⁻⁷ Magnesium hydride (MgH₂), which contains 7.6 mass% of hydrogen, is a promising candidate for hydrogen storage applications because of the relative abundance of Mg resources, low weight of Mg, and the high hydrogen content of MgH₂.⁸ However, its applications have been limited by its high operation temperature of 300 °C at an equilibrium pressure of 0.1 MPa and the slow hydrogen adsorption kinetics of bulk Mg.⁹ To overcome these drawbacks, most studies have focused on the preparation of Mg/MgH₂ nano/microstructures and nanocomposites.^{3,4,10-20} Mechanical milling of Mg/MgH₂ with appropriate elements, alloys, or compounds is the most widely used method for producing such Mg-based nanomaterials.^{3,16,17} These materials have greatly contributed to elucidating the relationship between reactivity and nanostructure. Although some doping or alloying techniques can affect the desorption temperature, this always lowers the hydrogen storage capacity because of the additional weight. With the milling technique, the particle size of MgH₂ can be reduced to several hundreds of nanometers while the grain size can be reduced to several tens of nanometers; however, in most cases, this is always accompanied by inhomogeneous size distributions, agglomeration, and impurities. Recently, Mg nanowires with diameters ranging from 30 to 170 nm were produced via a physical vapor-transport deposition method; these nanowires showed enhanced kinetics for hydrogen adsorption.⁴ Most significantly, the desorption energy of MgH₂ (energy needed for the dissociation of MgH₂ to Mg and H₂; it is 74 kJ/mol-H₂ for the bulk form), drastically decreased to 65.3 kJ/mol-H₂ for nanowires with diameters of 30–50 nm. Hydriding chemical vapor deposition (HCVD)¹⁸ is another method used to produce MgH₂ fibers (or wires in the nano/microscale) with high purity. These fibers were synthesized by depositing the vaporized Mg under H₂ atmosphere, as expressed by the gas-gas reaction:

The as-prepared MgH_2 fibers showed excellent H_2 storage properties.¹⁹ MgH_2/Mg nano/microstructures are expected to depend on temperature and hydrogen pressure.^{20,21} Historically, Dr. Ukichiro Nakaya of Hokkaido University, Sapporo, is world-famous for elucidating the relationship between the shape of snow crystals and the atmospheric conditions, i.e., temperature and supersaturation of the atmosphere.²² Weather conditions are now easily predicted thanks to the Nakaya diagram. In this respect, the synthesis of MgH_2/Mg nano/microstructures with shapes controlled under different temperature and hydrogen pressure may be of considerable interest for researchers in the field of hydrogen storage or batteries.²¹ The P-T diagram for MgH_2/Mg would be of great help in material design or mass production.

In this study, we carried out the controlled synthesis of MgH_2/Mg nano/microstructures. We succeeded in controlling the shapes (nanofibers, nanoparticles, microdendrites, irregular bulk, hexagonal microplates, and microspheres) and compositions of the products by adjusting the deposition temperature and H_2 pressure. The results were plotted on a thermodynamic P-T (pressure-temperature) diagram on basis of the dissociation of MgH_2 , as shown in Figure S1:

Thermodynamically, the white area denotes the stable phase of MgH_2 ; the shadowed area indicates MgH_2 dissociating into Mg and H_2 under high temperatures. Theoretically, we should be able to produce MgH_2 in the MgH_2 stable area and Mg in the decomposition area. More details are presented in the following sections.

Experimental section

MgH₂/Mg products were prepared from commercially available Mg (purity 99.9%, particle size < 75 μm) under a highly pure H₂ atmosphere (99.99999%). The experimental setup was modified from ref.²¹ as shown in Figure S2-(a): a cooler jacket running with cooled water was set around the left-hand flange of the Inconel tube reactor to produce a larger temperature distribution along the tube wall. A piece of stainless mesh (100 mesh, $\Phi 0.10 \times 100 \times 220$ mm, SUS304, Nilaco Ltd.) adhered along the tube wall was used as the substrate for collecting the products. Five grams of raw Mg were heated to vaporization at 600 °C under 1, 2, 3, and 4 MPa of H₂; the reactants of H₂ and Mg vapor were deposited onto the cooled substrate and formed MgH₂/Mg products. Heating times of 7, 13, and 20 h were used; after several hours of heating, the reactor was cooled down to room temperature in about 1 hour by a fan, during which time the H₂ pressure was kept consistent with that during the heating process.

The temperature distribution along the inner top of tube wall (with the mesh on) was measured beforehand under different H₂ pressures of 1, 2, 3, and 4 MPa. The temperature measuring apparatus (see Figure S2-(c)) consisted of six thermocouples (K-type, $\Phi 0.5$ mm) with spacings of 1.5, 1.5, 1.0, 1.5, and 1.5 cm; by moving the slider fastened on the fixing device, we were able to measure the temperatures of different positions along the mesh (inner top of the tube wall). The temperature distribution is shown in Figure S3 as a function of distance from the inner surface of the left-hand flange.

Deposits with widths of 2 cm on the mesh corresponding to the inner top part of tube wall were collected for characterization. The as-prepared samples were characterized by powder X-ray diffraction (XRD, Rigaku Miniflex, CuK α) for composition analysis and scanning electron microscopy (SEM, JEOL, JSM-6360LA) for morphology observation. The sample preparation methods for XRD and SEM observations as well as the reusing treatment of the mesh substrate are shown in Figure S2-(b). After collecting the products, the mesh was dipped into an HCl (0.1 mol L⁻¹) solution for several minutes with ultrasonic vibration and washed with distilled water and ethyl alcohol for several times, after which the mesh substrate was finally reused.

Results and discussions

MgH₂/Mg nano/microstructures were synthesized using the hydriding chemical vapor deposition (HCVD) method by controlling the hydrogen pressure and deposition temperature. Figure 1 shows the images of the products, which are inserted in the P-T diagram of MgH₂, deposited on the mesh under different H₂ pressures for a heating time of 7 h. The four samples clearly showed the same boundary at the position of 4.3 ± 0.1 cm distance from the left-hand flange (see Figure S4). By adjusting the temperature distribution (Figure S3), the product images were inserted into the P-T diagram of MgH₂ (Figure 1). On the right side of the boundary (4.3 ± 0.1 cm; line b in Figure 1), which is denoted as area 3 in Figure 1, the samples showed metallic shiny images, especially those deposited at low H₂ pressures; these may be metallic Mg. On the left side of the boundary, the samples showed a white color (area 2 in Figure 1), which can correspond to highly pure MgH₂; however, the samples were black on the low temperature side (area 1 in Figure 1), especially for those prepared at low H₂ pressures, which may indicate low purity of MgH₂. XRD patterns (Figure S5) confirmed these indicators: the metallic shiny substance deposited on the right side of the boundary (area 3 in Figure 1) was Mg, that was partially hydrogenated during the cooling process (in which the H₂ pressures were kept consistent with that in the heating process) after 7 h of heating; these samples showed higher intensity of MgH₂ at high H₂ pressures than that at low pressures. On the left side of the boundary, the white deposits (area 2 in Figure 1) showed highly pure MgH₂, especially those prepared under high H₂ pressures; however, far away from the boundary, at the low temperature side (area 3 in Figure 1), the samples showed decreasing purity of MgH₂ and were black in color (mixture of Mg and MgH₂). This clearly shows that Mg was deposited exactly on the right side of the boundary because MgH₂ is decomposed at higher temperatures, as shown in Figure S1 (the shadowed area). Obviously, highly pure MgH₂ was deposited near the boundary on the left side since thermodynamically it is a stable MgH₂ area. However, a mixture of MgH₂ and Mg was also produced on the low temperature side despite being in the MgH₂ stable area. This is explained later by the hydrogenation kinetics of Mg; the growth mechanism is also discussed.

The measured boundary for the MgH_2 and Mg stable areas is plotted by the red solid line in Figure 1 and compared with the theoretical dissociation pressure for MgH_2 , which is the black solid line. The measured boundary showed disagreement with the theoretical pressure as it was shifted to higher temperatures. The measured temperatures for separating the Mg and MgH_2 stable areas at 1, 2, 3, and 4 MPa were 396, 450, 481, and 501 °C, respectively, while the corresponding theoretical temperatures are 387, 427, 454, and 475 °C. Two reasons account for the shift: First, the fluctuation of the temperature distribution along the reactor tube wall caused by H_2 convection;²⁰ Second, since the products were cooled down to room temperature after several hours of heating while keeping the H_2 pressure constant, the original deposited Mg is partially hydrogenated during the cooling process. However, the measured and theoretical boundaries showed better agreement at the low H_2 pressure of 1 MPa (396 °C and 387 °C, respectively) than that at high H_2 pressures.

Scanning electron microscopy (SEM) was used to observe the morphology of the as-prepared samples at different H_2 pressures for different deposition temperatures. All of the results are summarized on the P-T diagram of MgH_2 shown in Figures 2 and 3 (Figure 3 is a simplified version of Figure 2; see also Figure S9 for more detailed information). Different shapes of crystals produced at different H_2 pressures and temperatures were classified into six distinct areas: (1) powder-shaped crystals at the nanoscale, where the powders are finer at low temperatures than that at high temperatures; (2) a mixture of powder, dendrite, root-like and curved coarse fibers at the microscale; (3) fiber-shaped crystals, that are curved and straight at the nano/microscale, in which the fibers are straighter and finer at higher pressures; (4) irregular bulk shapes at the microscale; (5) hexagonal shapes at the microscale; and (6) spherical shapes at the microscale.

Until now, we mainly concentrated on the results using a heating time of 7 h to summarize the relationship between the crystal morphology and deposition conditions, i.e. deposition temperature and H_2 pressure. We now demonstrate the kinetics and the growth mechanism here.

Figure 4 shows the images of the products deposited at 2 MPa with different heating times of 7, 13 and 20 h. As confirmed by the XRD analysis shown in Figure 5, prolonging the heating time caused the highly pure MgH_2 product area on the left side of the boundary (4.3 ± 0.1 cm) to shift to a lower temperature (left side). After 20 h of heating, all of the samples showed a single phase of MgH_2 ; we removed the subsequently deposited metallic shiny materials for 20 h of heating on the white product layer surface and the remaining product on the mesh was used for XRD analysis, which was compared with that of 7 and 13 h of heating; the reason is shown in the latter part about the metallic dendrite Mg crystals. Similar results for samples heated at 1 MPa are shown in the Supporting Information (Figures S6 and S7). Therefore, prolonging the heating time shifts line a in Figures 1 and 3 (only the composition information is considered), or for the boundary of areas 1 and 2, to the low temperature side; this enlarges the MgH_2 deposition area (area 2). This explains why we failed to produce highly pure MgH_2 in area 1 of Figure 1 with a heating time of 7 h, despite it being in the thermodynamically MgH_2 stable area.

The as-proposed gas-gas reaction at the deposition area shown in Eq. (1) should contain the following two steps in series:

Eq. (3) is the condensation of the vaporized Mg, and Eq. (4) is the hydrogenation of the solid Mg. The reaction rates for them are R_1 and R_2 , respectively. In the shadowed area of Figure S1 (the Mg stable area), only the condensation of the vaporized Mg occurred because MgH_2 is decomposed at high temperatures, where $R_1 \gg R_2$; therefore, we produced Mg at the high temperature condition of area 3 in

Figures 1 and 3. In the white area of Figure S1 (the MgH_2 stable area), the hydrogenation of solid Mg (Eq. (4)) at high temperature and high H_2 pressure conditions had a larger reaction rate than that at low temperature and low H_2 pressure conditions; at the same time, the condensation of the vaporized Mg at low temperature side had a larger reaction rate than that at high temperature side; therefore, at low H_2 pressures of 1 and 2 MPa and at lower temperatures, the products showed a mixture of MgH_2 and Mg, where the reaction rate $R_1 > R_2$ and the solid Mg accumulated. However, prolonging heating time allowed the previously unhydrided Mg to be hydrogenated. The V-S (vapor-solid) growth mechanism was introduced to explain the growth of MgH_2 nanofibers because no catalyst was used during the HCVD process.²¹ Combined with the two-step reaction in this study, the shapes of the deposited crystals must be determined by the first step of the Mg condensation. In the V-S mechanism, the shapes of the deposited crystals are affected by the concentration of the source vapor, deposition temperature (concentration of the source vapor and deposition temperature control the supersaturation degree of the source vapor), and deposition cooling rate. Various Mg structures, such as nanowires (curved and straight), spheres, flakes, rods, and sea urchin-like shapes, were successfully prepared by changing the temperature for Mg evaporation and the flow rate of Ar carrier gas in a physical vapor-transport deposition method.^{4,5} The vapor source concentration and deposition temperature (and thus different levels of supersaturation) were also found to influence the morphology of MgO grown by the V-S method.^{23,24} In our experiments, the Mg raw material was heated to vaporization in the evaporation area at 600 °C under H_2 pressures of 1, 2, 3, and 4 MPa. Two reactions are expected to occur in this area:

Clearly, the concentration of Mg vapor supplied was higher at low H₂ pressures than that at high H₂ pressures. The results showed that in the MgH₂ stable area, a high H₂ pressure and temperature condition was advantageous for producing uniform and thin MgH₂ nanofibers. Fibrous highly pure MgH₂ was produced under 4 MPa H₂ at the temperatures near the theoretical dissociation temperature, where there was a large reaction rate due to a low concentration of Mg vapor and high H₂ pressure; and the reaction rate $R_2 > R_1$, the MgH₂ nanofibers seemed to grow from the direct gas-gas reaction as shown in Eq. (1).

We observed a metallic shiny material deposited on the surface of the white MgH₂ near the boundary of 4.3 ± 0.1 cm at a heating time of 20 h under H₂ pressures of 1 and 2 MPa; the area is indicated by a rectangle in Figure S8. The metallic shiny material had various dendrite shapes similar to the dendrite Mg prepared in our previous study.²¹ Due to the long deposition time, the product layer grew thicker, and the temperature on the layer surface was higher than that on the mesh, which may shift to the MgH₂ decomposition area. This is also why the results after 7 h of heating were used to summarize the relationship between the crystal morphology and the deposition conditions for temperature and H₂ pressure.

Conclusions

In summary, we carried out the shape-controlled growth of MgH_2/Mg nano/microstructures by hydriding chemical vapor deposition (HCVD). We were easily able to control the shape of the products by adjusting the deposition temperature and H_2 pressure. The results were plotted on a thermodynamic P-T diagram for MgH_2 . Different shapes of crystals having different compositions were prepared at different temperatures and pressures. The growth mechanism for the HCVD method was discussed both thermodynamically and kinetically. The results shown in the P-T diagram will allow us to determine the optimum conditions for synthesizing different shapes of products by HCVD, and this may lay the foundation for the mass production of nano/microsized MgH_2/Mg for use in hydrogen storage or batteries.

Shape-controlled growth of MgH_2/Mg nano/microstructures via hydriding chemical vapor deposition (HCVD) was achieved by adjusting the deposition temperature and H_2 pressure. Different shapes of crystals having different compositions were prepared at different temperatures and pressures. The results were plotted on the thermodynamic P-T diagram of MgH_2 , which allows us to determine the optimum conditions for synthesizing different shapes of products by HCVD.

Figure 1. Deposited product images on the mesh inserted on the P-T diagram of MgH_2 . These images were edited to adjust the temperature distribution and sample compositions (more information see Figure S3, Figure S4, and Figure S5). The products were synthesized under H_2 pressures of 1, 2, 3 and 4 MPa, respectively, at a heating time of 7 h. The black solid line is the theoretical dissociation pressure of MgH_2 as a function of temperature, and the red solid line was plotted using the experimental results. Area 1 is a mixture of MgH_2 and Mg; area 2 (between the two red lines) is a highly pure MgH_2 area; and area 3 is Mg. Prolonging the heating time shifts line a to low temperatures (left side) and enlarges the MgH_2 deposition area (area 2).

Figure 2. Morphology of the deposited products at different deposition temperatures and H_2 pressures inserted on the P-T diagram of MgH_2 . The black solid line shows the theoretical dissociation pressure of MgH_2 as a function of temperature. The black dash lines enclose the measurable area in this experiment corresponding to the product images in Figure 1. (More detailed information about the morphology of the deposited products, see Figure S9)

Figure 3. Simplified morphology and composition distributions of the deposited products at different deposition temperatures and H_2 pressures plotted in the P-T diagram of MgH_2 . The composition distribution information is based on the results at a heating time of 7 h. The black solid line shows the theoretical dissociation pressure of MgH_2 as a function of temperature, and line b is plotted using the experimental results. The black dash lines enclose the measurable area in this experiment corresponding to the products images in Figure 1. Area 1 is a mixture of MgH_2 and Mg having powder, dendrite, root-like, and curved fibrous shapes. Area 2 is highly pure MgH_2 having curved and straight fiber shapes. Area 3 is Mg having irregular, hexagonal, and spherical shapes. When only the composition information is considered, prolonging the heating time shifts line a to low temperatures (left side) and enlarges the MgH_2 deposition area (area 2).

Figure 4. Images of the products deposited on the mesh synthesized under H_2 pressure of 2 MPa at different heating times of 7, 13, and 20 h. Insets show the XRD sample preparation and the composition distribution based on the XRD results in Figure 5.

Figure 5. XRD patterns of the samples synthesized at different deposition temperature areas under 2 MPa of H_2 at heating times of 7, 13 and 20 h. The sample numbers correspond to that in Figure 4. MgO peaks were due to exposure of the samples to the air during measuring, and the unhydrogenated Mg was partially oxidized.

Metallic shiny Mg deposited under 1 MPa with a heating time of 20 h

Figure S8. Metallic shiny materials separated from the as-deposited white product (MgH_2) near the boundary of 4.3 ± 0.1 cm. The heating time was 20 h at 1 MPa H_2 . The one at 2 MPa with heating time of 20 h have the similar dendrite crystals.

SEM images of the metallic shiny material

(9).

Figure S9. Detailed morphology information of the deposited products at different deposition temperatures prepared at different H₂ pressures.
