Abstract

Estimation of overhead production enrichment in continuous foam separation was conducted with a surfactant: sodium *n*-dodecylbenzenesulfonate (SDBS), and soluble proteins: ovalbumin (OA) and hemoglobin (HB). Axial profiles of the volumetric flow rate and the concentration of the collapsed foam liquid within the column were measured, and the enrichment ratio and the liquid holdup in axial direction were determined experimentally. The proposed model was fitted to the experimental results obtained with various experimental conditions (superficial gas velocity, feed concentration, and pH) and was in reasonable agreement with the experimental data by using the least square regression. The present model makes it possible to estimate the foamate concentration at a desired foam height.

Keywords: Adsorption; Bioseparations; Bubble Columns; Separation; Foam separation; Protein

1. Introduction

The foam separation technique has been widely used in ore flotation [1], waste water treatment [2], and food and biochemical industries [3-7]. Especially this technique is useful to enrich objective surface-active substances from dilute aqueous solution. The enrichment process is mainly dominated by (i) adsorption of objective substances onto bubble surface within bubble dispersed bed and (ii) drainage within foam bed.

It has been well known empirically that concentration of foamate (collapsed foam liquid) increased exponentially in the axial direction within the foam because of liquid film thinning and drainage of liquid in foam due to gravitational acceleration and plateau border suction. This fact suggests that the concentration of the liquid in the foam will be changed with the overflowing and the sampling position in the axial direction of the column. It is important to estimate the degree of the enrichment at each axial positions for operating this technique.

Many investigators proposed the model for liquid drainage in foam. Hartland and Barber [8] proposed a model for cellular foams in batch foaming system by considering the liquid holdup in the cellular foam proposed the physical model. Kumar and Desai [11-13] have proposed a model which has been considered thinning of the liquid film, the plateau border suction and the axial/lateral directions of liquid flow in foam. Narsimhan and Ruckenstein [14,15] developed the drainage model based on the model proposed by Desai and Kumar [11]. Other mathematical and physical models on liquid drainage in foam have been reported [16-19]. These models have physical and mathematical rigidity, however, these make it difficult to use with ease practically because of mathematical complexity

and many parameters.

In this study, a simple model for estimation of the enrichment within foam bed in axial direction was proposed with two parameter. Continuous foam separation experiments were conducted with sodium *n*-dodecylbenzenesulfonate (SDBS), ovalbumin (OA) and hemoglobin (HB). The proposed model will be verified with the experimental results.

2. Description of enrichment model

2.1. Enrichment ratio in foam bed

In continuous foam separation, the concentration, C_f , of the collapsed foam liquid is expressed as the following equation from the mass balance:

$$C_f = \frac{S_f X + \varepsilon C_b}{\varepsilon}, \quad (1)$$

where, ε and S_f are the liquid holdup and surface area of bubbles per unit volume in the foam bed at height H from the liquid-foam interface, respectively. C_b is the concentration of the bulk liquid in the column. X is the adsorption density on bubble surface. Enrichment ratio is defined as:

$$E \equiv \frac{C_f}{C_b}. \quad (2)$$

Approximately, the liquid holdup can be expressed as:

$$\varepsilon = S_f \delta. \quad (3)$$

δ is the thickness of liquid film. Moreover, X is expressed by Langmuir's type isotherm [20-22]:

$$X = \frac{K\gamma C_b}{1 + KC_b}, \quad (4)$$

where, K and γ represent the equilibrium adsorption constant and the saturated surface density, respectively. The following relationship is derived from Eqs. (1) - (4):

$$S_f = \frac{\varepsilon(E-1)(1 + KC_b)}{\gamma K}. \quad (5)$$

Then, if variation in S_f in foam height is small, that is, assuming that the surface area, S_{f0} , of bubbles at liquid-foam interface within the column is mostly equal to S_f [22, 23], the following relationship is also derived from Eq. (5):

$$E - 1 = \frac{S_{f0}\gamma K}{\varepsilon(1 + KC_b)}. \quad (6)$$

Therefore, if variation in ε in axial direction can be known, variation in E will be determined.

2.2 Liquid holdup in foam bed

Assuming that the decreasing rate of the liquid holdup is proportional to the present liquid holdup, the next relationship is obtained as:

$$\frac{d\varepsilon}{dt} = -\alpha\varepsilon, \quad (7)$$

where α is decreasing rate coefficient. Relationship between the superficial gas velocity, u_g , and rising velocity, v , of gas is expressed as:

$$u_g = v(1 - \varepsilon). \quad (8)$$

In foam bed, gas (bubbles) accompany with liquid in foam, therefore, rising velocity of the liquid in foam should be equal to v . In the present conditions, the liquid holdup is sufficiently smaller than 1, thus, the rising velocity of the foam within the column will seem to be equal to the superficial gas velocity. Therefore, displacement of the foam for dt is expressed as:

$$dH = v dt = u_g dt. \quad (9)$$

From Eqs. (7) and (9), the next equation is obtained.

$$\left(\frac{1}{\varepsilon}\right)d\varepsilon = -\left(\frac{\alpha}{u_g}\right)dH. \quad (10)$$

By solving Eq. (10) with an initial condition ($\varepsilon = \varepsilon_0$ at $H = 0$),

$$\varepsilon = \varepsilon_0 \exp\{-(\alpha/u_g) H\}. \quad (11)$$

ε_0 is the liquid holdup at the liquid - foam interface ($H = 0$).

2.3. Determination of parameter

Finally, the following equation is obtained from Eqs. (6) and (11):

$$\ln(E - 1) = \ln \frac{S_{f0} \gamma K}{\varepsilon_0 (1 + KC_b)} + \frac{\alpha}{u_g} H . \quad (12)$$

Plot of $\ln(E-1)$ versus H will give a straight line. By comparing the experimental values with Eq. (11), α and ε_0 will be determined, and S_{f0} will be also determined by intercept of Eq. (12).

3. Experiments

3.1. Materials

Ovalbumin (egg white) (OA) was purchased from Eastman Kodak Company or Difco Laboratories. Hemoglobin from bovines (HB) and sodium *n*-dodecylbenzenesulfonate (SDBS) were purchased from Wako Pure Chemical Industries, Ltd. (Japan). These were used without further purification. The ion strength and pH of protein solutions were adjusted with NaCl at 5×10^{-3} M and with aqueous HCl or NaOH to several desired values.

3.2. Experimental setup

A foam column used in this study was almost the same apparatus as described in the previous studies [22-24]. The column was constructed of a transparent acrylic resin tube of 4.4 cm inside diameter and 95 cm in height. A sintered glass filter with average pore size from 10 to 15 μm was installed as a gas distributor at the bottom of the column. Nitrogen gas was supplied to the column through the distributor as bubbles. In the experiments, a foam collector was equipped at the top of the column to entrap foam generated from the liquid surface. Pressure taps for measuring gas holdup in the column were along the wall installed at intervals of 25 cm.

3.3. Experimental procedures

The procedures are also almost the same as those described in our previous paper [22]. The solutions were charged into the column from a feed tap by a quantitative pump. The volumetric flow rate of feed liquid was $0.5 \text{ cm}^3/\text{s}$. After confirming a steady state in the bulk liquid, sampling of the foam liquid for measuring the volumetric flow rates and the concentrations was started. The concentrations of SDBS and proteins (OA or HB) were measured spectrophotometrically (JASCO U-best30) at 220 nm and by the Lowry method [25], respectively. The pH of the bulk liquid in the column was measured with a pH meter (ORION Model SA 520). The gas holdup was determined from the difference in static pressure between the clear and aerated liquids using a differential pressure transducer. Voltage signals were recorded by a personal computer (NEC PC-9801VM) via A/D converter (CONTEC).

4. Results and Discussion

4.1. Surface area of bubbles in foam bed

The ε was determined from the next relationship:

$$\varepsilon = \frac{W_f}{W_f + Au_g} . \quad (13)$$

W_f and A are the volumetric flow rate of the liquid in foam within the column and the cross-sectional area of the column, respectively. Typical results of S_f are shown in Fig. 1. Plotting points (all keys) in Fig. 1 were calculated by Eq. (5). K and γ used in the calculation are summarized in Table 1. The values of K and γ for OA and HB were determined by continuous foam separation experiments [22]. The value of these for SDBS was also determined by the same method in the present study. The value of γ for SDBS was mostly close to the values in literature [26,27]. The scatters of data for OA and HB should be caused by the measurement error of W_f . In case of HB, although remarkable coalescence of bubbles within the foam was not observed visually, however, the foam of HB seemed to be more dry and cellular foam rather than the foam of OA. Therefore, more high concentration region had to be employed in case of HB. In comparison with values of γ for OA and HB at i.e.p., γ for OA is 1.5-fold larger than that for HB (Table 1). This may affect that OA foam seems to be more stable than HB foam in Fig. 1. As shown in the figure, S_f was not varied widely in the axial direction. Thus, S_f seemed to be constant in the present experimental conditions for SDBS, OA and HB.

4.2. Verification of the present model

Typical experimental results of the liquid holdup, ε , are shown in Fig. 2. ε decreased abruptly and exponentially near the liquid-foam interface ($H = 0$). This tendency was almost the same as observations reported in literature [10-19]. The slope of ε increased with decreasing C_b . The solid lines in the figure were obtained by fitting of the data to Eq. (11). the calculated values agreed well with the experimental ones by giving adequate values for α and ε_0 . Fig. 3 shows fitting of the data to Eq. (12). Solid lines in this figure are the calculated values by Eq. (12). Good agreement between the experimental values and the calculated ones was recognized. These results would support the validity of the present model.

4.3. Parameters estimated from the present model

Fig. 4 shows change in α in function of C_b . α should reflect a degree of drainage of liquid through the liquid film. α tended to decrease with increasing C_b . In comparison with value of α for SDBS (Fig. 4(a)) and proteins (Fig. 4(b); OA and HB), protein foam seemed to be stable and wet comparatively in lower bulk concentration region. In Fig. 4(b), influence of pH was slightly observed at pH 4.6 for OA (open triangle). and at pH 6.0 for HB (open circle and open diamond). a values for these are lower than that for the other pH for OA and HB, respectively. At the pH (4.6 for OA and 6.0 for HB), the value of K is largest than that at the other pH.

In the present experimental conditions, the surface tension value were 6.5×10^{-2} - 4.9×10^{-2} and 6.5×10^{-2} - 4.4×10^{-2} N/m for proteins and SDBS, respectively, which were not varied widely. The values of liquid viscosity also hardly varied (0.9 - 1.1×10^{-3} kg/(m s)). Slightly change in surface tension and liquid viscosity would greatly affect α . At this point, we cannot exactly explain what physical properties of the liquids affect the foam stability from the present experimental data and our analysis. Some literature have pointed out that surface viscosity was one of important factor concerning foam stability and liquid drainage within foam [11, 12, 28, 29], although we could not measure it.

The foam at the liquid-foam interface was considered to be consisted by accumulation of bubbles rising through the column and liquid films around bubbles. Thus, the liquid holdup, ε_0 , at liquid-foam interface can be expressed as:

$$\varepsilon_0 = 1 - \left(1 + \frac{\delta_0}{r_b} \right)^{-3} . \quad (14)$$

Where, δ_0 and r_b represent the thickness of the liquid film around one bubble and the radius of the bubble accumulated at the liquid-foam interface within the column, respectively. The r_b was determined by the following equation, because r_b was considered to equal to the radius of bubbles rising through the bulk liquid within the column [22-24]:

$$r_b = \frac{u_g}{2\varepsilon_g(1-\varepsilon_g)^{4.65} \left[\left(\frac{4}{225} \right) \cdot \frac{(\rho_l - \rho_g)^2 g^2}{\mu_l \rho_l} \right]^{\frac{1}{3}}}, \quad (15)$$

where ε_g , g , ρ_l , ρ_g , and μ_l represent the gas holdup in the bubble dispersion phase, the gravitational acceleration, the densities of liquid and gas, and the viscosity of the liquid, respectively. Fig. 5 shows the relationship between ε_0 and r_b . Solid lines in the figure were calculated from Eq. (14). The δ_0 for both SDBS and proteins (OA and HB) were determined by a least squares method, in this case, values of δ_0 for both SDBS and proteins were 8 and 20 μm , respectively. ε_0 would be explained by the relationship of Eq. (14), although some scatters were observed. Influence of pH on ε_0 and r_b for both OA and HB was not observed in Fig. 5 because of some scatters. This suggests that ε_0 was mostly affected by bubble size. The most estimated r_b for proteins concentrated in the range of from about 0.05 to 0.09 cm and the data scattered appreciably. This reason cannot be clarified for the present. However, Eq. (14) can represent the tendency of change in ε_0 adequately for the present system.

5. Conclusions

The axial enrichment ratio profile in foam bed for continuous foam separation column were studied and can be expressed by the present model. Good agreement between the experimental results of the axial enrichment profiles and the calculated values was obtained for both proteins (ovalbumin (OA) and hemoglobin (HB)) and sodium *n*-dodecylbenzenesulfonate (SDBS) by determining the two model parameters using least squares method. α was mostly influenced by the concentration of the bulk liquid, that is, slightly change in surface tension and liquid viscosity would greatly affect α . The liquid holdup, ε_0 , at the liquid-foam interface within the column was expressed in function of the bubble radius, r_b , and the thickness, δ_0 , of the liquid film, and δ_0 was estimated 8 and 20 μm for SDBS and proteins, respectively. The present model can relatively ease to estimate the enrichment in axial direction of foam height in continuous foam separation. Further development and study are required for application of the present model to the other substances or experimental conditions to confirm the verification of the present model.

Notation

A	= a cross-sectional area of bubble column	$[\text{m}^2]$
C_b	= equilibrium concentration of the bulk liquid in bubble column	$[\text{kg}/\text{m}^3]$
C_f	= the concentration of the liquid in foam within the column	$[\text{kg}/\text{m}^3]$
r_b	= bubble radius	$[\text{m}]$
E	= enrichment ratio defined by Eq. (2)	$[-]$
H	= foam height	$[\text{m}]$
g	= gravitational acceleration	$[\text{m}/\text{s}^2]$
K	= equilibrium adsorption constant	$[\text{m}^3/\text{kg}]$
S_f	= bubble surface area in foam per unit volume	$[\text{m}^2/\text{m}^3]$
S_{f0}	= bubble surface area at liquid-foam interface per unit volume	$[\text{m}^2/\text{m}^3]$
u_g	= superficial gas velocity	$[\text{m}/\text{s}]$
v	= rising velocity of bubble in foam bed	$[\text{m}/\text{s}]$
W_f	= the volumetric flow rate of the liquid in foam	$[\text{m}^3/\text{s}]$
X	= adsorption density	$[\text{kg}/\text{m}^2]$

Greek symbols

α	= decreasing rate coefficient	$[\text{s}^{-1}]$
δ	= thickness of liquid film	$[\text{m}]$
ε	= liquid holdup in foam bed	$[-]$
ε_0	= liquid holdup at liquid-foam interface	$[-]$
ε_g	= gas holdup in bubble dispersed phase	$[-]$
γ	= saturated adsorption density	$[\text{kg}/\text{m}^2]$
μ	= liquid viscosity	$[\text{kg}/(\text{m s})]$

ρ_g	= gas density	[kg/m ³]
ρ_l	= liquid density	[kg/m ³]
