(Received 22 June 2004; published 12 October 2004)

We propose a ballistic spin interferometer using a square loop (SL) geometry, where an incident electron wave packet is split into a pair of partial waves by a “hypothetical” beam splitter. These electron partial waves, then, follow the SL path in the clockwise and counterclockwise directions, respectively, so that they interfere with each other at the incident point, retaining the spin degree of freedom. We find that the backscattering probability of an incident electron can be largely modulated by varying the magnitude of the Rashba spin-orbit coupling constant \( \alpha \). We propose to make the proposed spin interferometry experiment using an artificial nanostructure fabricated in, for example, In\(_{0.52}\)Al\(_{0.48}\)As/In\(_{0.53}\)Ga\(_{0.47}\)As/In\(_{0.52}\)Al\(_{0.48}\)As quantum wells.

Exploitation of spin degree of freedom for the conduction carriers provides a key strategy for finding new functional devices in semiconductor spintronics.1–4 A promising approach for manipulating spins in semiconductor nanostructures is the utilization of spin-orbit (s.o.) interactions. In this regard, lifting of the spin degeneracy in the conduction (or valence) band due to the structural inversion asymmetry is especially called “Rashba effect,”5,6 the magnitude of which can be controlled by the applied gate voltages and/or specific sample design of the heterostructure.7,8

In the present work, we propose a ballistic spin interferometer (SI) using a square loop (SL) geometry, where an electron spin rotates by an angle \( \theta \) due to the Rashba effect as it travels along a side of the SL ballistically. The use of the SL geometry for a SI is contrasted with our previous proposal of a SI using a ring (circular) geometry.4 There, we assumed that electrons in the interferometer travel along the curvature of the ring ballistically as well as adiabatically (without scattering), retaining both the dynamical spin phase and the geometrical Berry phase. In reality, experimental verification of such a SI has not been an easy task9–11 because (1) electrons have to travel along the whole circle of the ring without scattering in order for us to see the predicted spin interference effect and (2) the universal conductance fluctuation (UCF),12 which is caused by the presence of randomly distributed elastic scatterers in the ring, would cover the signal of the spin interference. It is expected that these hurdles found in a SI using a circular loop would be circumvented in a SI using SL’s. In a SL geometry, (1) electrons are required to travel ballistically only along sides of the SL. Electrons would, then, experience spin-preserving scattering (reflection) at each corner of the SL. This makes the consideration of the geometrical Berry phase unnecessary, because the spin preserving reflection of electrons is a nonadiabatic process, which simplifies the model calculation. (2) Other advantages of using SL’s include the geometrical feasibility of two-dimensional arraying for diminishing the effects of the UCF and the Aharonov-Bohm (AB) oscillation13 as we discuss later.

An electronic band structure for a two-dimensional electron gas (2DEG) that is confined in an potential well sufficiently asymmetric to induce the Rashba effect has a spin splitting in the conduction band. We are aware of another mechanism that induces spin splittings due to the bulk inversion asymmetry, so-called “Dresselhaus term,”14 which we leave as a future research topic. The energy dispersion relation for a system with the Rashba effect is given by

\[
E = \hbar^2 k_x^2/2m^* \pm \alpha k_x,
\]

where \( \alpha \) is the Rashba spin-orbit coupling constant and + and – signs are for spin up and down states, respectively, for a given wave vector \( \mathbf{k} \).

We propose a ballistic spin interferometer using a square loop (SL) geometry, where an incident electron wave packet is split into a pair of partial waves by a “hypothetical” beam splitter. These electron partial waves, then, follow the SL path in the clockwise and counterclockwise directions, respectively, so that they interfere with each other at the incident point, retaining the spin degree of freedom. We find that the backscattering probability of an incident electron can be largely modulated by varying the magnitude of the Rashba spin-orbit coupling constant \( \alpha \). We propose to make the proposed spin interferometry experiment using an artificial nanostructure fabricated in, for example, In\(_{0.52}\)Al\(_{0.48}\)As/In\(_{0.53}\)Ga\(_{0.47}\)As/In\(_{0.52}\)Al\(_{0.48}\)As quantum wells.

We see that \( \Psi_{k1} \) can be written as a product between the plane-wave part \( e^{i\mathbf{k}_1 \cdot \mathbf{x}} \) and the spin state vector part...
which exemplifies the motion of spin precession as $\Psi_k$ propagates along $x$ axis:

$$
\frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ i \\ -1 \\ i \\ \end{pmatrix}
\rightarrow
\frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ i \\ -1 \\ i \\ \end{pmatrix}
\rightarrow
\text{and so on.}
$$

The quantum mechanical state of the incident electron (before passing through the beam splitter) can be written as

$$
\Psi = \left( \begin{array}{c} \Psi_1 \\ \Psi_2 \end{array} \right) = \left( \begin{array}{c} \alpha \\ \beta \end{array} \right),
$$

where $\left( \begin{array}{c} \alpha \\ \beta \end{array} \right)$ represents a general spin state vector $(\alpha \alpha^* + \beta \beta^* = 1)$ using the spin basis along $z$ axis. The property of the beam splitter introduced above is defined by the following unitary operator:

$$
U = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},
$$

where $I$ denotes the $2 \times 2$ identity matrix. Thus, we apply $U$ to $\Psi$.

$$
U\Psi = \left( \begin{array}{c} \frac{1}{\sqrt{2}} \alpha \\ \frac{1}{\sqrt{2}} \beta \end{array} \right) = \left( \begin{array}{c} \Psi_1 \\ \Psi_2 \end{array} \right).
$$

We note that partial waves $\Psi_1$ and $\Psi_2$, subsequently, propagate through the SL path in the clockwise (CW) and counterclockwise (CCW) directions, respectively.

Now, we consider the interference between the partial waves $\Psi_1$ and $\Psi_2$ when they come back to the incident point after passing through the SL paths. It is noted that the plane-wave parts of the CW and CCW paths are related to each other by the time reversal symmetry, i.e., the time reversal path of the CW path is the regular CCW path, and vice versa. The interference of this type manifests itself in (1) the weak localization (or weak antilocalization) phenomena in diffusive conductors and (2) the magnetoresistance oscillation with a period corresponding to the magnetic flux half quanta $\Phi_0=\hbar/2e$, denoted as the Al'tshuler-Aronov-Spivak (AAS) oscillation. From Eq. (1), we can see that both partial waves $\Psi_1$ and $\Psi_2$ acquire an equal phase factor $e^{ikL}$ from the plane-wave part after passing through the SL path, where $L$ is the side length of the SL. Therefore, we can safely neglect the plane wave part of the wave function when discussing the spin interference effect in the present SI.

Let $\Psi_{\text{CW}}$ describe the electron spin that emerges on path 2 as a result that partial wave $\Psi_1$ passes through the CW path:

$$
\Psi_{\text{CW}} = e^{i\theta} R_{\hat{z}}(\theta) R_{\hat{x}}(\theta) R_{\hat{y}}(\theta) \Psi_1
$$

$$
= e^{i\theta L} \text{ A} \Psi_1 \rightarrow \text{ path 2,}
$$

where $R_\theta(\theta)$'s $(\hat{\xi} = \pm \hat{x}, \pm \hat{y})$ denote quantum mechanical rotation operators for spin $1/2$ about $\hat{\xi}$ direction by an angle $\theta$ applying the right-handed screw rule.

$$
R_\theta(\theta) = I \cos \frac{\theta}{2} - i \hat{\xi} \cdot \sigma \sin \frac{\theta}{2},
$$

where $\sigma$ is the vector expression of the Pauli spin matrices. In Eqs. (5) and (6), $\theta$ is the spin precession angle that an incident spin pointing $+z$ direction would experience while traveling through a side of the square in the presence of the
Rashba effect ($\theta = 2\Delta kL$) and $e^{i\phi/2}$ is the phase factor acquired from the vector potential that is responsible for the magnetic field $B$ ($B\parallel \hat{z}$) piercing the SL ($\phi = 2eBL^2/h$). In a similar way, $\Psi_{CCW}$ is the spin state vector describing the partial wave that emerges on path 1 as a result that partial wave $\Psi_2$ passes through the CCW path:

$$\Psi_{CCW} = e^{-i\phi/2}A^{-1}\Psi_2 \rightarrow \text{path 1}.$$  \hspace{1cm} (7)

$\Psi_{CW}$ and $\Psi_{CCW}$ hit the beam splitter from path 2 and path 1, respectively, and form the final (interfered) state for the electron wave,

$$\Psi_{\text{final}} = \left[ \begin{array}{c} \Psi_1' \\ \Psi_2' \end{array} \right] = U^{-1} \left[ \begin{array}{c} \Psi_{CCW} \\ \Psi_{CW} \end{array} \right] = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} e^{-i\phi/2}A^{-1}\Psi_2,$$  \hspace{1cm} (8)

where we used the unitarity of $U$. We find,

$$\Psi_1' = \frac{1}{2} \begin{pmatrix} e^{-i\phi/2}A^{-1} + e^{i\phi/2}A \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} X + Y \cos \theta/2 \alpha + (1 - i)Y \sin \theta/2 \beta \\ (1 + i)Y \sin \theta/2 \alpha + (X - Y \cos \theta/2) \beta \end{pmatrix},$$  \hspace{1cm} (9)

where $X = \cos(\phi/2)[\cos^2(\theta/2) + \sin^2(\theta/2)[\cos^2(\theta/2) - \sin^2(\theta/2)]$, and $Y = 2\sin(\phi/2)\sin^2(\theta/2)\cos(\theta/2)$. We note that the probability that an incident wave $\Psi_1$ is backscattered to path 1 is given by the inner product $\langle \Psi_1' | \Psi_1' \rangle$, which is a function of the initial spin state $(\alpha, \beta)$. We consider the spin interference effect for the case that an incident electron is spin unpolarized. We let

$$\begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \begin{pmatrix} \cos \frac{\xi}{2} e^{i\chi/2} \\ \sin \frac{\xi}{2} e^{-i\chi/2} \end{pmatrix},$$  \hspace{1cm} (10)

and calculate the expectation value of $\langle \Psi_1' | \Psi_1' \rangle$ for an unpolarized incident spin using the following formula:

$$\langle \text{physical quantity} \rangle = \frac{1}{4\pi} \int_0^\pi \sin \xi \, d\xi \int_0^{2\pi} \, d\chi$$

$$\times \langle \text{physical quantity to be averaged} \rangle.$$  \hspace{1cm} (11)

We shall see that $\langle \Psi_1' | \Psi_1' \rangle$ contains terms proportional to $|\alpha|^2 - |\beta|^2$, $\alpha^* \beta$, and $\alpha \beta^*$. It is easily shown that the expectation values of these terms become zero for an unpolarized incident spin using Eq. (11). We finally obtain

FIG. 2. Amplitude of the oscillatory part of the backscattering probability $\langle \Psi_1' | \Psi_1' \rangle$ in the proposed spin interferometer as a function of the spin precession angle $\theta$ along a side of the square loop.

$$\langle \Psi_1' | \Psi_1' \rangle = X^2 + \left( 1 + \sin^2 \frac{\theta}{2} \right) Y^2$$

$$= \frac{1}{2} + \frac{1}{4}(\cos^4 \theta + 4 \cos \theta \sin^2 \theta + 2 \cos 2\theta)\cos \phi$$

$$= \frac{1}{2} + A(\theta)\cos \phi.$$  \hspace{1cm} (12)

We note that the oscillation of $\langle \Psi_1' | \Psi_1' \rangle$ as a function of $\phi$ corresponds to the AAS oscillation in mesoscopic physics, whose amplitude is given by $A(\theta) = \frac{1}{4}(\cos^4 \theta + 4 \cos \theta \sin^2 \theta + 2 \cos 2\theta)$ in the present calculation. We plot $A(\theta)$ as a function of $\theta$ in Fig. 2.

Experimentally, we propose to fabricate an array of micron-sized SL’s in In$_{0.52}$Al$_{0.48}$As/In$_{0.53}$Ga$_{0.47}$As quantum wells (QW) using conventional nanolithographic techniques, where we investigate the amplitude of the AAS oscillation around $B=0$ as a function of the applied gate voltage. We illustrate an example of the SL array sample in Fig. 3, where electrons in the shaded region are depleted by the nano fabrication process. The undepleted white region consists of six SL’s and every neighboring pair of the loops is electrically connected at the middle of the side. Note that the incident electrons are injected from the sides of the SLs in Fig. 3, not from the corners as we assumed in the theoretical model. In fact, our further theoretical investigation showed that the magnitude of $ \langle \Psi_1' | \Psi_1' \rangle $ does not depend on where to inject the incident electron in the perimeter of the SL. Therefore, the gate-voltage dependence of the AAS oscillation amplitude for a sample described by Fig. 3 should still be predicted by $A(\theta)$.

In an actual SL array sample, the length $L$ should ideally be smaller than the electron mean free path $l$, though it still has to be large enough for the spin precession angle $\theta$ to be gate-controllable to a significant extent. Values of $L$ about 1.5 $\mu$m would satisfy these requirements at $T=0.3$ K. The width $W$ for the channel should be smaller than $L$, though, of which values should be optimized experimentally. In actual samples, the number of SL’s that should be arrayed two-dimensionally is much larger than six in order to diminish quantum fluctuations (QF’s) like (1) the AB oscillation with
In a QW system with the Rashba effect, spin precession angle $\theta$ is given by

$$\theta = 2\Delta k L = \frac{2e\alpha L}{\hbar^2}.$$  \hspace{1cm} (13)

In the In$_{0.52}$Al$_{0.48}$As/In$_{0.53}$Ga$_{0.47}$As/In$_{0.52}$Al$_{0.48}$As QW system, the magnitude of $|\alpha|$ is typically $2 \times 10^{-12}$ eV m. The variation of $\alpha$ value that can be achieved by the applied gate voltage is approximately $\pm 5 \times 10^{-13}$ eV m. For example, for sample 3 in Ref. 8, using $m^* = 0.047 m_0$ (the effective mass at Fermi energy) and $L = 1.8 \mu$m, $\theta$ can be varied from 0.29$\pi$ to $\pi$ (the corresponding $\alpha$ values are $0.4 \times 10^{-12}$ eV m and $1.4 \times 10^{-12}$ eV m, respectively) by the applied gate voltage. With this variation of $\theta$, we see that the value of $A(\theta)$ is also varied from the minimum value $A(\theta) = -0.5$ for $\theta = 0.64 \pi$ to the maximum value $A(\theta) = 0.5$ for $\theta = \pi$. This result predicts that the amplitude of the AAS oscillation should be drastically modulated (sometimes even change signs) by the applied gate voltage in the actual experiments.

In summary, we propose a ballistic spin interferometer using a square loop (SL) geometry. In this model, a pair of electron partial waves is created by a “hypothetical” beam splitter at the incident point of the interferometer, where one partial wave follows the square path in the clockwise direction and the other does in the counterclockwise direction. These partial waves, then, meet each other again at the incident point, where the spin interference should take place. We propose to use a SL array fabricated in In$_{0.52}$Al$_{0.48}$As/In$_{0.53}$Ga$_{0.47}$As/In$_{0.52}$Al$_{0.48}$As quantum wells to test the results of the present model calculation, where the $\alpha$ (Rashba constant) values in this material system have been already studied quantitatively using the weak antilocalization analysis.\(^8\)
