Effects of Irradiance and Water Temperature on the Photosynthesis and Growth of the Crustose Coralline Alga Lithophyllum yessoense Foslie (Corallinales, Rhodophyceae)

Shigeo ICHIKI1), Hiroyuki MIZUTA1), Hajime YASUI1) and Hirotoshi YAMAMOTO1)

Abstract

The effects of irradiance and water temperature on the photosynthesis and growth of Lithophyllum yessoense, which is extensively dominant in the sublittoral zone in southwestern Hokkaido, Japan, were examined in the laboratory. The maximum net photosynthesis rate ($P_{\text{max}}$) was about 16 \( \mu \text{g} \ \text{O}_2 \cdot \text{cm}^{-2} \cdot \text{h}^{-1} \) at 15-25°C. The compensation irradiance ($I_c$) and saturating irradiance ($I_s$) of L. yessoense were considerably reduced as the water temperature decreased, and initial slope ($a$) was highest at 5°C. The net photosynthesis was relatively high at low water temperatures under any irradiance except in the dark. This physiological adaptability to low irradiance at low water temperatures would allow this alga to grow in the severe limitation of irradiance of winter and early spring in southwestern Hokkaido. However, the $I_c$ and $I_s$ increased at high water temperature, showing a strong dependence on a high irradiance. The results indicate that L. yessoense is not adapted to grow in a dim environment, such as a macroalgal canopy.

Key words: Crustose coralline alga, Lithophyllum yessoense, Photosynthesis, Growth

Introduction

Lithophyllum yessoense grows extensively in the sublittoral zone of southwestern Hokkaido, Japan (Adye et al., 1976; Masaki, 1984). The total coverage of this alga is 79% at Taisei in this area (Fujita, 1989). An extensive area covered with a large amount of crustose corallines without fleshy macroalgae is generally referred to as a Coralline flat (Ayling, 1981). The predominance of crustose corallines prevents the recruitment of other macroalgae, such as Laminaria Lamiourex and Undaria Suringar by its epithallial sloughing (Masaki et al., 1981, 1984) and its released allelochemicals (Denboh et al., 1997; Suzuki et al., 1998). Studying the adaptability of crustose corallines to light and water temperature is necessary to prevent the decrease in macroalgae in southern Hokkaido (Tamura, 1951).

The photosynthesis rate has been studied in many crustose corallines to estimate the carbon production (Johansen, 1981). Fujita (1988) showed seasonal changes in photosynthesis and respiratory rates of L. yessoense at four seasons. However, no information exists on specific photosynthesis characteristics of L. yessoense in a laboratory culture, nor on the relationships between the photosynthesis rate and the environmental conditions, such as irradiance and water temperature.

The presence or absence of coralline algae, as well as the characteristics of their growth, are largely influenced by environmental conditions (Johansen, 1981). The effects of irradiance and water temperature on the growth of sporelings of L. yessoense have been examined (Notoya, 1978; Fujita, 1986; Ichiki et al., 2000). Fujita et al. (1992) observed the regenerating growth of L. yessoense. However, no report exists of the effects of irradiance and water temperature on the growth of adult thalli of this alga.

Here, we describe the effects of irradiance and water temperature on the photosynthesis and growth of adult thalli of L. yessoense in a laboratory culture, and we discuss the relationships among photosynthesis, growth and environmental conditions (water temperature and irradiance).

Materials and Methods

Lithophyllum yessoense for the photosynthesis experiment was collected in the sublittoral zone at Kumaishi in December 1999 and for the growth experiment in April and May 2000, when the water temperatures were about 10°C. The water temperature along the coast of the Japan Sea ranges from 4°C to 23°C (Hokkaido Aquaculture Development Authority, 1999). The plants for photosynthesis experiment were pre-cultured at 15°C using bubbling under 83 \( \mu \text{mol} \ \text{photons} \cdot \text{cm}^{-2} \cdot \text{s}^{-1} \) (14L : 10D) with a white fluorescent lamp for 6-9 days.
to arrange the amount of pigments (Ramus and Zimmerman, 1977) and for the growth experiment for 20–38 days to lessen influences of the rapid growth by the regeneration (Fujita et al., 1992). 1/4 concentration of PES medium without vitamins was used for the culture and photosynthesis measurements, and 0.25 mg l⁻¹ GeO₂ and 1 ml l⁻¹ antibiotic mixture (Tatewaki et al., 1989) were added to this medium to inhibit the growth of diatoms and bacteria. The medium was changed every 10 days. Seawater was filtered through a glass fiber filter (Whatman GF/C 0.44 μm, Whatman, Maidstone, UK) and was autoclaved at 120°C for 15 minutes.

**Photosynthesis**

The algal size was adjusted to ca. 1.5 cm² at 3 days before the photosynthesis measurements. Photosynthesis was measured using the dissolved oxygen method with an oxygen electrode (Model 57, YSI). After 30 minutes of acclimatization, the fluctuation of dissolved oxygen in a glass bottle (25 ml) agitated with a stirrer was monitored for 30 minutes. The water temperature was adjusted to 5, 10, 15, 20, 25 and 30°C using a Coolronics (Komatsu-yamato) under 0, 16.6, 83, 166, 415 and 830 μmol photon⁻¹ m⁻² s⁻¹ of a tungsten lamp, and 36 conditions were set for the different combinations of water temperature and irradiance. The photosynthesis parameters were expressed from photosynthesis-irradiance (P-I) curves using the equation (Gómez et al., 1998),

\[ P(I) = P_{n_{max}} \tanh (\alpha I / P_{n_{max}}) + R, \]

where \( P(I) \) is the gross photosynthesis rate expressed in μg O₂ cm⁻² h⁻¹; \( P_{n_{max}} \) is the maximum net photosynthesis; \( \tanh \) is the hyperbolic tangent; \( \alpha \) is the initial slope estimated by the least square method using six to nine data at limiting irradiance; \( I \) is the irradiance and \( R \) is the respiration in the dark. The saturating irradiance \( (I_e) \) was calculated from the intersection between the \( P_{n_{max}} \) and \( \alpha \). The compensation irradiance \( (I_c) \) corresponded to the intersection between the curve and x-axis (y=0).

**Growth**

The effect of irradiance was examined under 8.3, 16.6, 41.5, 83, 166 and 332 μmol photon⁻¹ m⁻² s⁻¹ (14L : 10D) at 15°C. The effect of water temperature was examined at 5, 10, 15, 20 and 25°C under 83 μmol photon⁻¹ m⁻² s⁻¹ (12L : 12D). The plants were acclimated by culture for 10 days at each experimental condition with bubbling. The culture medium was changed every 10 days.

Microscopic pictures were taken to record the thallus growth in vertical section on the first and on the 40th day of culture, so that the same part of a thallus could be traced. The length from the edge of section to thallus margin was measured. The marginal growth rate was calculated using the equation,

\[ \text{Marginal growth rate} = 100 \times \frac{(L_2 - L_1)}{(t_2 - t_1)} \]

where \( L_1 \) and \( L_2 \) are the length at times \( t_1 \) and \( t_2 \), respectively.

The least square method was used to estimate the coefficient correlation (\( r^2 \)) between the water temperature and the photosynthesis characteristics and between the marginal growth rate and the photosynthesis characteristics.

**Results**

**Photosynthesis**

Fig. 1 shows net photosynthesis-irradiance relationships at 5–30°C. The photosynthesis rates increased with increase in irradiance and were saturated at 166–415 μmol photon⁻¹ m⁻² s⁻¹. Photoinhibition did not occur even at 830 μmol photon⁻¹ m⁻² s⁻¹ at all water temperatures.

Table 1 summarizes the photosynthesis characteristics. The maximum gross photosynthesis rate \( (I_{\alpha_{max}}) \) increased with the increase in water temperature up to 25°C, reaching 45.9 μg O₂ cm⁻² h⁻¹, about 3.5 times that at 5°C. The respiration rate \( (R) \) increased with increase in water temperature, showing a significant correlation (p<0.01) between water temperature and \( R \) (Table 2); it was 32.6 μg O₂ cm⁻² h⁻¹ at 30°C, about 11 times that at 5°C. The maximum net photosynthesis rate \( (P_{n_{max}}) \) at 15°C was 17.1 μg O₂ cm⁻² h⁻¹, the highest of all the conditions, although it was similar to those at 20°C and 25°C; it was 10.1 μg O₂ cm⁻² h⁻¹ at 5°C, about 7 times that at 30°C. The compensation irradiance \( (I_c) \) increased with increase in water temperature, showing a significant correlation (p<0.01) between water temperature and \( I_c \) (Table 2). It was 121 μmol photon⁻¹ m⁻² s⁻¹ at 30°C, about 23 times that at 5°C. The saturating irradiance \( (I_e) \) at 20°C was 172.8 μmol photon⁻¹ m⁻² s⁻¹, the highest of all the conditions, and was 7.4 times that at 5°C. The photosynthesis efficiency (\( \alpha \)) was 0.56 at 5°C, and was less than 0.28 at other water temperatures.

Fig. 2 shows net photosynthesis-temperature relationships at irradiances between 0 and 830 μmol photon⁻¹ m⁻² s⁻¹. The optimum water temperatures for photosynthesis were 25°C under 830 μmol photon⁻¹ m⁻² s⁻¹, 15°C under 415 μmol photon⁻¹ m⁻² s⁻¹, 10°C under 166 μmol photon⁻¹ m⁻² s⁻¹, 5–15°C under 83 μmol photon⁻¹ m⁻² s⁻¹, and 5°C under 16.6 μmol photon⁻¹ m⁻² s⁻¹. The net photosynthesis rate at 5°C was about a half that at 25°C under 830 μmol photon⁻¹ m⁻² s⁻¹. The net
photosynthesis rates at 5°C under all irradiances ranged from 6.3 μg O₂·cm⁻²·h⁻¹ to 10.1 μg O₂·cm⁻²·h⁻¹, but the rate was from −15.3 μg O₂·cm⁻²·h⁻¹ to 16.5 μg O₂·cm⁻²·h⁻¹ at 25°C.

Growth

Fig. 3 shows the relationship between marginal growth rate and irradiance. The marginal growth rate increased with increase in irradiance up to 83 μmol photon·m⁻²·s⁻¹, under which it was 16.2 μm·day⁻¹, the

highest of all irradiances.

Fig. 4 shows the relationship between the marginal growth rate and water temperature. The marginal growth rate increased with increase in water temperature from 5°C to 20°C, reaching 23.5 $\mu$m $\cdot$ day$^{-1}$ at 20°C, about 10 times that at 5°C; it was 15.1 $\mu$m $\cdot$ day$^{-1}$ at 25°C. The marginal growth rate was correlated significantly with $I_a$ positively ($p<0.05$) and with $\alpha$ negatively ($p<0.05$, Table 2).

Discussion

Productivity

The $P_{n\text{ max}}$ of L. yessoense acclimated in a laboratory culture was similar to that obtained by Fujita (1988). The maximum $P_{n\text{ max}}$ of this alga was one to three times those of other crustose corallines (e.g. Porolithon onkodes (Heydricht) Foslie, Neogoniolithon solubile (Foslie et Howe) Setch. & Mason) in coral reefs (Littler and Doyt, 1975; Wanders, 1976). However, the marginal and accretive growth rates of crustose corallines in coral reefs (Finckh, 1904; Adey and Vassar, 1975; Matsuda, 1989) are more than five times those of L. yessoense (Fujita, 1990; Ichiki, 2001). The results show that the yields of photosynthates do not always reflect the growth rates in crustose corallines. The maximum $P_{n\text{ max}}$ of L. yessoense was about a half that of Laminaria religiosa Miyabe, which dominates in southwestern Hokkaido (Matsuyama, 1985).

Saturated irradiance for photosynthesis and growth

Growth and photosynthesis were saturated under 83 $\mu$mol photon $\cdot$ m$^{-2}$ $\cdot$ s$^{-1}$ and 415 $\mu$mol photon $\cdot$ m$^{-2}$ $\cdot$ s$^{-1}$ at 15°C, respectively. The discrepancies of these saturated irradiances between growth and photosynthesis have been reported for many macroalgae (Lüning, 1981). The saturated irradiance for the growth of adult thalli was about one-third that of the sporelings of this alga (Ichiki et al., 2000), indicating that the growth of adult thalli is less dependent on the higher irradiance than the sporelings.
Fig. 3. Relationships between marginal growth rate of *Lithophyllum yessoense* and irradiance. Symbols represent mean values \( (n=8) \). Vertical bars indicate standard errors.

Fig. 4. Relationships between marginal growth rate of *Lithophyllum yessoense* and water temperature. Symbols represent mean values \( (n=8) \). Vertical bars indicate standard errors.

**Optimum water temperature for photosynthesis and growth**

The optimum water temperature for the growth of *L. yessoense* was 20°C, which was similar to that of the sporelings of this alga reported by Ichiki et al. (2000). The growth of this alga was inhibited at 25°C, similar to the results for sporelings of this alga found by Fujita (1986) and Ichiki et al. (2000). However, the optimum water temperature for gross photosynthesis was recorded at 25°C, showing a different optimum water temperature between the gross photosynthesis and the growth. The optimum water temperature for photosynthesis disagrees with that for growth in some arctic seaweeds (Healey, 1972). However, the optimum water temperature for the growth in this study agreed with that for \( I_o \) in *L. yessoense*, showing a significant positive correlation between the marginal growth rate and \( I_o \). Such results
suggest that the degree of dependence on the irradiance reflects the growth of *L. yessoense*. Difficulties in measuring the extreme slow growth of crustose corallines cause a lack of data on the growth rate (Garrabou and Ballesteros, 2000). Accordingly, we think that the *I*ₐ is a useful indicator of the growth activity of crustose corallines.

Adaptability to water temperature and irradiance

*I*ₐ shows some correlation with algal habitat, and α is a useful indicator of the light quantum yield (Lobban and Harrison, 1994). The *I*ₐ and *I*ₙ of *L. yessoense* were considerably reduced as the water temperature decreased, and α was highest at 5°C. The net photosynthesis was relatively high at low water temperatures under any irradiance except in the dark. This physiological adaptability to low irradiance at low water temperature would allow this species to grow in the severe limitation of irradiance, such as at low sun irradiation, short photoperiods and enormous epiphytes, such as diatoms, to grow on this alga (per. obs.), which all occur during winter and early spring in southwestern Hokkaido. However, the *I*ₐ and *I*ₙ increased at high water temperature, showing a strong dependence on high irradiance. In southwestern Hokkaido, the irradiance under a sparse *L. religiosa* canopy on a solstitial day, when the water temperature is about 15°C (Hokkaido Aquaculture Development Authority, 1999), is about 80 µmol photon·m⁻²·s⁻¹ (Fujita, 1988), which is less than *I*ₐ (126.6–172.8 µmol photon·m⁻²·s⁻¹) and similar to *I*ₙ (44.9–91.3 µmol photon·m⁻²·s⁻¹) at 15-25°C for *L. yessoense*. Accordingly, these facts support the suggestions by Fujita (1988) that *L. yessoense* is not adapted to grow under a *L. religiosa* canopy formed from late spring to autumn in southwestern Hokkaido.
