Key words: ZNRF1; tubulin; ubiquitin; RING-finger; zinc-finger
Abstract

The ubiquitin-proteasome system has been implicated in neuronal degeneration and regeneration. We demonstrated that overexpression of ZNRF1, which has been identified as a crucial molecule in nerve regeneration, causes morphological changes such as neurite-like elongation. Molecular dissections showed that both the RING finger domain and zinc finger domain are required for morphological changes. Furthermore, we identified β-tubulin type 2 (Tubb2) as a ZNRF1-binding protein by yeast two-hybrid screening. In vivo binding assay showed that ZNRF1 interacts with tubb2 and immunofluorescent staining suggests that ZNRF1 is colocalized with tubb2. These results suggest that ZNRF1 mediates regulation of neuritogenesis via interaction with tubulin.
Introduction

The ubiquitin-mediated proteolytic pathway plays an important role in the elimination of short-lived regulatory proteins, including those that contribute to the cell cycle, cellular signaling, secretion, organelle biogenesis, DNA repair, and morphogenesis [1]. Ubiquitin conjugation is catalyzed by enzymes designated as ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin ligase (E3) [2]. E3 is thought to be the component of the ubiquitin conjugation system that is most directly responsible for substrate recognition [1]. On the basis of structural similarity, E3 enzymes have been classified into three families: HECT (homologous to E6-AP COOH terminus) family [3], RING finger-containing protein family [4, 5] and U-box family [6].

In the nervous system, the ubiquitin-proteasome pathway is thought to play an important role to ensure proper neuronal function including neuritogenesis and neurodegeneration [7, 8]. Ubiquitin-mediated degradation not only removes misfolded proteins in the subcellular regions of neurons to prevent the development of neurodegenerative diseases but also mediates transduction of intracellular signaling. It has been reported that neurite outgrowth was induced by proteasome inhibitors, suggesting that neurite outgrowth requires an enhanced pool of ubiquitinated proteins or ubiquitin-dependent proteolysis of a negative regulator of neurite outgrowth in vitro [8].

It has been reported that ZNRF1, identified as one of the nerve injury-induced genes, contains a zinc finger and RING finger domain and is predominantly expressed
in the nervous system [9] and that ZNRF1 is localized in the endosome-lysosome compartment in fibroblasts [10]. ZNRF1 has an E3 ubiquitin ligase activity and the RING finger domain is required for its activity.

In this study, we found that overexpression of ZNRF1 causes morphological changes such as neurite-like elongation. Furthermore, we identified β-tubulin type 2 (Tubb2) as a ZNRF1-binding protein by yeast two-hybrid screening, and immunofluorescent staining verified that ZNRF1 is colocalized with Tubb2. These findings suggest that ZNRF1 regulates morphological changes of neurons via interaction with tubulin.
Materials and methods

Cell culture. HEK293T, COS-7 and HeLa cell lines were cultured under an atmosphere of 5% CO₂ at 37°C in DMEM (Sigma) supplemented with 10% fetal bovine serum (Invitrogen).

Cloning of cDNAs and plasmid construction. Mouse ZNRF1 and Tubb2 cDNAs were amplified from mouse brain cDNA by PCR with KOD-Plus (Toyobo) using the following primers: 5’-AACATGGGGGGCAAGCAGAGC-3’ (ZNRF1-sense), 5’-GGGTCAGTCAGCAGGGTGCTC-3’ (ZNRF1-antisense), 5’-ACCATGCGCGAGATCGTGCAC-3’ (Tubb2-sense) and 5’-TTCTCAAGCCTCATCTTCACC-3’ (Tubb2-antisense). The amplified fragments were subcloned into pBluescript II SK+ (Stratagene). ZNRF1 cDNA tagged with a carboxy-terminal FLAG tag or Myc tag was cloned into pCMV (Sigma) or pcDNA3 (Invitrogen). Tubb2 cDNAs with an HA tag at the amino terminus were cloned into pCGN. Deletion mutants of ZNRF1 corresponding to 1-144 or 138-227 amino acid residues were generated by PCR, and ZNRF1 mutants (C145A and C184A) were generated by using a QuikChange mutagenesis kit (Stratagene).

Transfection, immunoprecipitation and immunoblot analysis. HEK293T cells were transfected by the calcium phosphate method. After 48 h, the cells were lysed in a solution containing 50 mM Tris-HCl (pH 7.4), 150 mM NaCl, 1% Triton-X 100, leupeptin (10 μg/ml), 1 mM phenylmethylsulfonyl fluoride, 400 μM Na₃VO₄, 400 μM EDTA, 10 mM NaF, and 10 mM sodium pyrophosphate. The cell lysates were
centrifuged at 16,000×g for 20 min at 4°C, and the resulting supernatant was incubated with antibodies for 2 h at 4°C. Protein A-Sepharose (Amersham Biosciences, Piscataway, NJ) that had been equilibrated with the same solution was added to the mixture, which was then rotated for 1 h at 4°C. The resin was separated by centrifugation, washed five times with ice-cold lysis buffer, and then boiled in SDS sample buffer. Immunoblot analysis was performed with the primary antibodies, horseradish peroxidase-conjugated antibodies to mouse or rabbit immunoglobulin G (1:20,000 dilution, Promega Corporation, Madison, WI) and an enhanced chemiluminescence system (ECL, Amersham Pharmacia) [6]. The following antibodies were used: mouse monoclonal anti-Myc antibody (9E10, Roche Molecular Biochemicals), mouse monoclonal anti-HA antibody (HA.11/16B12, Covance Research Products) and rabbit polyclonal anti-FLAG antibody (Sigma).

**Immunofluorescent staining.** Cells on a glass cover were fixed for 20 min at room temperature with 4% formaldehyde in PBS and then incubated for 1 h at room temperature with primary antibodies in PBS containing 0.1% bovine serum albumin and 0.1% saponin. They were then incubated with Alexa488-labeled goat polyclonal antibodies to mouse immunoglobulin or Alexa546-labeled goat polyclonal antibodies to rabbit immunoglobulin (Molecular Probes) at a dilution of 1:2,000. The cells were covered with a drop of GEL/MOUNT (Biomed) and then photographed with a CCD camera (DP71, Olympus) attached to an Olympus BX51 microscope [6]. To detect endogenous tubulin, the cells were permeabilized with 100% acetone at -20°C for 4 min and then stained with anti-β-tubulin antibodies (Cell Signaling Technology) [11].
**Yeast two-hybrid screening.** Complementary DNA encoding amino acids 1–144 of mouse ZNRF1 was fused in-frame to the nucleotide sequence for the LexA domain (BD) in the yeast two-hybrid vector pBTM116, and yeast strain L40 (Invitrogen) stably expressing the corresponding pBTM116 vector was transfected with a mouse brain Matchmaker cDNA library (Clontech) by the lithium acetate method.

**Semiquantitative RT–PCR.** The expression levels of ZNRF1 were evaluated by semiquantitative reverse transcription–polymerase chain reaction (RT-PCR). In brief, total RNA was extracted from cultured cells using ISOGEN reagent (Nippon gene) according to the manufacturer’s instructions and was used to generate cDNA by reverse transcription with ReverTra Ace (Toyobo). The resulting cDNA was amplified by PCR with KOD-plus (Toyobo) using the following primers:

- 5’-AGCATGGGGGCAAGCAGAGC-3’ (human and monkey ZNRF1-sense),
- 5’-AGGTCAGTCCGCAGGGTGTTC-3’ (human and monkey ZNRF1-antisense),
- 5’-ACCACAGTCCATGCCATCAC-3’ (GAPDH-forward) and
- 5’-TCCACCACCTGTTGCT-GTA-3’ (GAPDH-reverse). The PCR mixtures were initially denatured at 94°C for 2 min, followed by denaturation for 15 s at 94°C, primer annealing for 30 s at 64°C, and extension for 1 min at 68°C for 30 cycles (for ZNRF1) or 22 cycles (for GAPDH).

**Statistical analysis.** We used the unpaired Student's t test to determine the statistical significance of experimental data.
**Results**

*Overexpression of ZNRF1 causes morphological changes*

It has been reported that ZNRF1 proteins are located in the endosome-lysosome compartment in fibroblasts [10]. We examined the subcellular localization of ZNRF1 proteins in another cell line by immunofluorescent staining. We transfected an expression vector encoding carboxy-terminal Myc-tagged ZNRF1 into COS-7 cells. Immunofluorescent staining showed that Myc-tagged ZNRF1 is diffusely localized in the cytosol. More amazingly, overexpression of ZNRF1 caused changes in cell shape (neurite-like elongation). We verified morphological changes in HEK293T and HeLa cells by overexpression of Myc-tagged ZNRF1 (Fig.1A). We found that the shape of COS-7 cells was dramatically changed compared to that of HEK293T or HeLa cells. To clarify differences in the effects among these cell lines, we measured the expression levels of ZNRF1 mRNA in these cell lines. Semi-quantitative analysis using RT-PCR showed that ZNRF1 mRNA was expressed in these cell lines and that ZNRF-1 is highly expressed in COS-7 cells compared with the expression level of HEK293T or HeLa cells (Fig. 1B and C). These findings suggest that a high level of ZNRF1 expression is related to cell morphological changes.

*RING finger domain is required for morphological changes*
ZNRF1 has a putative myristoylation sequence at the amino terminus and a zinc finger domain and a RING finger domain at the carboxy-terminal half. It has been reported that ZNRF1 has an E3 ubiquitin ligase activity and requires the RING finger domain for its activity. To examine which region is required for the morphological change, we constructed several deletion mutants or point mutants of ZNRF1 (Fig. 2A). A previous study indicated that ZNRF1(C184A), in which Cys184 in a RING finger domain is substituted for Ala, has no E3 ubiquitin ligase and that ZNRF1(C145A), in which Cys145 in a zinc finger domain is substituted to Ala, likely causes its conformation. It has been reported that the amino-terminal domain with myristoylation is required for localization to the endosome-lysosome [10]. To inhibit amino-terminal myristoylation, ZNRF1 tagged with an N-terminal Myc-tag was also generated (Fig. 2A). Immunoblot analysis with anti-Myc antibody showed that wild-type and mutants of ZNRF1 proteins were expressed in transfected cells (Fig. 2B). We next transfected expression vectors encoding GFP, ZNRF1(FL) or mutants of ZNRF1 into COS-7 cells (Fig. 2C) and then counted the number of cells in which neurite-like projection is larger than its cell body (Fig. 2D). ZNRF1(ΔZinc/RING) and ZNRF1(C184A) sometimes caused cause cell morphological change, whereas ZNRF(C145A) or ZNRF1(138-227) had only a partial effect. Amino-terminal Myc-tagged ZNRF1 (Myc-ZNRF1(FL)) showed almost the same effect as that of carboxy-terminal Myc-tagged ZNRF1 (ZNRF1(FL)-Myc). These findings suggest that the RING finger domain of ZNRF1 is required for morphological changes and that the amino-terminal half of ZNRF1 and zinc finger domain are also partially important for this activity.
ZNRF1 interacts with Tubb2

To clarify the mechanism by which ZNRF1 affects cell morphology, we tried to identify the protein interacting with ZNRF1 by yeast two-hybrid screening. We screened a mouse brain cDNA library using mouse ZNRF1(ΔZinc/RING) as a bait. Consequently, fifty-five positive clones were isolated from $2.2 \times 10^6$ transformants. One of the positive clones had sequence identities with mouse β-tubulin type 2 (Tubb2, also known as Mβ2), which is one of the major components of microtubules. We confirmed that ZNRF1 interacts with Tubb2 by using a β-galactosidase assay (Fig. 3A). Next, we investigated whether ZNRF1 physically interacts with Tubb2 in mammalian cells. We transfected expression vectors encoding Myc-tagged ZNRF1 and/or HA-tagged Tubb2 into HEK293T cells. Cell lysates were subjected to immunoprecipitation with an antibody to Myc and the resulting precipitates were subjected to immunoblot analysis with an antibody to HA. An in vivo binding assay showed that Tubb2 interacts with ZNRF1(FL) and ZNRF1(ΔZinc/RING) but not with ZNRF1(138-227). These results indicate that ZNRF1 specifically interacts with Tubb2 via the amino-terminal region (Fig. 3B).

ZNRF1 colocalizes with tubulin

To verify the intracellular localization of ZNRF1 and Tubb2, we performed
immunofluorescent staining of FLAG-tagged ZNRF1 and HA-tagged Tubb2. Immunofluorescent staining showed that FLAG-tagged ZNRF1 is colocalized with HA-tagged Tubb2 (Fig. 4A). Furthermore, to confirm the interaction with endogenous tubulin, we performed immunofluorescent staining. We transiently transfected cells with expression vectors encoding GFP and carboxy-terminal Myc-tagged ZNRF1 and then stained them with anti-Myc or anti-β-tubulin antibodies. Immunofluorescent staining showed that Myc-tagged ZNRF1 is localized with endogenous tubulin arranged on microtubules (Fig. 4B). These findings indicate that ZNRF1 interacts with tubulin and is localized with microtubules.
Discussion

In this study, we showed that ZNRF1 interacts with Tubb2, one of the members of the β-tubulin family. β-tubulin is the major structural component of the microtubule network inside cells. It has been reported that Tubb2 transcripts are abundantly expressed in the adult mouse brain [12]. ZNRF1 is also highly expressed in the central nervous system, particularly in the developing cortical plate in embryos, indicating that ZNRF1 and Tubb2 may play an important role in the nervous system. It has also been reported that the mRNA expression of Tubb2 was elevated within two weeks after crushing the sciatic nerve [13], and ZNRF1 was identified as a gene induced after sciatic nerve injury [9]. These findings suggest that the collaboration of ZNRF1 with Tubb2 regulates axonal guidance or elongation after nerve injury.

We newly found that ZNRF1 induces cell morphological changes and that a RING finger domain is required for this neurite-like elongation. Unfortunately, we could not show ubiquitination of Tubb2 or acceleration of the turnover of Tubb2 by ZNRF1 (data not shown). However, since a RING finger domain of ZNRF1 is important for E3 ubiquitin ligase activity and for morphological changes, we cannot rule out the possibility that proteins other than Tubb2 are substrates for ZNRF1. It has also been reported that a large multidomain E3 ubiquitin ligase Phr1 is associated with the microtubule cytoskeleton within neurons and selectively localizes to axons but is excluded from growth cones and that motor and sensory neurons from Magelllan mice in which the Phrl gene is mutated displays abnormal morphologies. It has been reported
that the E3 ubiquitin ligase Parkin, the gene of which has several mutations in autosomal-recessive juvenile Parkinsonism (ARJP), binds to tubulin heterodimers and accelerates degradation of \(\alpha\)- and \(\beta\)- tubulin [14], resulting in possible protection by Parkin of neurons from the toxic accumulation of misfolded tubulin. Taken together, tubulin modification by ubiquitination may be important for neuritogenesis and intracellular quality-control for neurons.

We previously reported that interaction between U-box type ubiquitin ligase E4B and FEZ1 in mammalian cells was enhanced by coexpression of constitutively active PKC\(\zeta\) and that E4B mediated the polyubiquitination of FEZ1. Expression of a dominant-negative mutant of E4B in rat pheochromocytoma PC12 cells resulted in inhibition of neurite extension induced either by nerve growth factor or by coexpression of FEZ1 and constitutively active PKC\(\zeta\) [15]. Others have reported that the E3 ubiquitin ligase Smurf1, which regulates cell polarity and protrusive activity via PKC\(\zeta\)-dependent recruitment to cellular protrusion sites, enhances neurite outgrowth [16]. Therefore, it may be important to investigate the relationship between ZNRF1 and PKC\(\zeta\) in order to clarify the mechanism by which morphological change is induced by overexpression of ZNRF1.

In conclusion, ZNRF1 is a novel regulator affecting cell morphology, and results of further studies on ZNRF1 may be useful for revealing neuronal degeneration or regeneration.
