We investigate theoretically the transport characteristics of a single electron transistor affected by the dynamic deformation of the device configuration due to phonons. By considering changes in capacitances and tunnel resistances caused by the breathing and oblong vibrations of the island that forms part of the transistor, we formulate the electron-phonon interaction peculiar to the device and derive its transport properties by means of the master equation. For a single electron transistor with a gold nanoparticle island of radius 1 nm, we demonstrate the contribution to the transport properties that originates from tunneling channels associated with THz phonon emission and absorption.

I. INTRODUCTION

It is well known that electron-phonon interactions affect the electronic states in a solid, which leads to a rich variety of transport phenomena. It is also well established that the transport properties of nanoscale electronic devices can depend on the geometry of the system. A useful tool for investigating the geometry and the electronic structure in molecular junctions is inelastic electron tunneling that occurs as a consequence of electron-phonon interactions in the junction.

In molecular devices, electron tunneling couples with vibrations of molecules in two ways; electron tunneling induces internal vibrations owing to rearrangement of atomic configuration, and the charged molecules are driven in the bias electric field. The coupling between the vibrations and tunneling cause phonon mediated electron transport channels, giving rise to characteristic I-V curves owing to multi-phonon emission and absorption.

The effect of phonons on the electron transport properties of a metal-based single electron transistor (SET) is more limited since the nano particle is too stiff to allow the atomic configuration changes in accordance with tunneling like the molecular devices, and then phonons do not couple with electron tunneling. For such devices operated in the Coulomb blockade regime, the electron-phonon interaction causes electron energy fluctuations that based on the bulk electron-phonon interaction are independent of the system size. Hence, with except for the translational vibrations of molecule, electron transport characteristics that reflect multi-phonon emission and absorption are not expected in the device.

In spite of that, we anticipate phonon mediated transport properties similar to the molecular devices due to a different type of electron-phonon interaction. The nano particle island is positioned in the vicinity of the electrodes, where the gaps between the island and electrodes set the key electronic parameters for the SET; the capacitances and tunnel resistances. Surface displacement of the particle island due to phonons modifies the gaps, which is expected to remarkably affect the current through the SET.

In this paper we investigate the effects of gap modulation on the electron transport in the SET. To understand the character and magnitude of possible phonon effects, we consider an ideal SET containing a metal nano particle between the source and drain. (Fig. 1) Such a system might be realized by attaching the particle to the electrodes with bio-molecules such as RNA or DNA. The metal island is assumed to be a sphere that supports a variety of acoustic phonon modes (Appendix A). The particle has an almost stress free surface and will have relatively large amplitude surface vibrations due to phonons. In particular, only the breathing modes of spherical symmetry change the intrinsic capacitance of the island and the oblong modes modify tunnel resistances significantly more than other modes, as discussed below. Considering these, we investigate the contributions of breathing and oblong mode phonons to the transport, respectively, as the representative cases.

Thanks to the nature of the attachment, the particle might move in a shuttle fashion between the electrodes. This translational shuttle motion also changes the capacitances and tunnel resistances. In order to differentiate these
effects from those of surface vibrations, we will assume the particle to be firmly fixed centrally between the electrodes. We also note that the system considered here is different to that of an SET used in a nano electromechanical system as a means to transduce the subtle motion of a nano resonator\textsuperscript{21–25}. In that situation the SET itself is taken to have rigid components and the transduction generally occurs via modulation of the coupling capacitance between the resonator and the SET island\textsuperscript{22}.

The paper is planned as follows; In Sec. II, we describe the system to be studied in this work, and introduce the Hamiltonian of the system. The phonon mediate tunneling is formulated in this section. In Sec. III, dealing with the phonon mediate tunneling as perturbation, the non-perturbed part of the Hamiltonian is diagonalized by means of a canonical transform. In Sec. IV, the density matrix and associated master equations are introduced. In Sec. V, we give numerical results for the thermal and transport properties. Finally, Sec. VI provides a discussion and summary of the work. Derivation of acoustic phonon modes in the particle is given in the Appendix.

II. MODEL

We consider a SET containing a gold spherical particle $a$ in radius, which is suspended centrally between the source and drain made of conducting planes(Fig. 1). The electron transport is due to single electron tunneling between the metal particle and the electrodes in the Coulomb blockade regime. The metal particle is connected to a heat bath, whose coupling strength is $γ_{\infty}$. Although the heat bath is depicted separately from the electrodes in Fig. 1, the electrodes may act as the heat bath.

![FIG. 1: Model of a SET. The nano metal particle is linked electrically to the source and drain made of conducting planes. $C_{L(R)}$ and $R_{L(R)}$ are the capacitance and tunnel resistance between the particle and the left (right) electrode, respectively. $a$ and $c$ are the radius of the metal particle and the distance between the particle and the leads. The oval below the particle indicates a heat bath.](image)

The Hamiltonian $H$ of the SET is given by

$$H = H_L + H_R + H_D + H_T + H_{ph} + H_b + H_{ph-b},$$

(1)

where $H_L$, $H_R$ and $H_D$ are the Hamiltonians of electrons in the source, the drain and the particle, respectively, and $H_T$ is the tunnel Hamiltonian;

$$H_L = \sum_k (\varepsilon_{L,k} + eV) c_{L,k}^\dagger c_{L,k},$$

(2)

$$H_R = \sum_k \varepsilon_{R,k} c_{R,k}^\dagger c_{R,k},$$

(3)
We estimate the capacitance between a metal sphere and a conducting plane, using the method of images. The subscript \( \alpha \) means the source for \( \alpha = L \), the drain for \( \alpha = R \), and the particle for \( \alpha = D \). \( V \) is the bias voltage and \( e (> 0) \) is the elementary charge. \( t_0^\alpha \) in \( H_T \) [Eq. (5)] is the coefficient of tunneling, and the factor \( \exp \left( \frac{r-a}{\lambda} \right) \) is introduced to express the modulation of tunnel resistance, considering that both the breathing and oblong modes expand or shrink the left and right gaps between the island and electrodes. Here \( r \) is the radius of the particle, including the surface displacement \( u_r \) due to phonons;

\[
r = a + u_r,
\]

and \( \lambda \) is a characteristic length of tunneling.

For the breathing mode phonons, \( r \) is independent of solid angles, and then the nanoparticle remains to be a sphere after deformation. We estimate the capacitance between a metal sphere and a conducting plane, using the method of images\(^{26} \) as

\[
C_{\text{sphere}}(r) = 4\pi e^e \varepsilon_0 r \left( 1 + \alpha + \alpha^2 \frac{1}{\alpha^2} + \ldots \right),
\]

(7)

where \( \alpha = \frac{a}{r} \). Here \( c \) is the distance between the center of the particle and the conducting plane, and then \( \alpha < \frac{1}{2} \).

The total capacitance \( C(r) \) in Eq. (4) of the SET composes \( C_L \) and \( C_R \), each of which is given by Eq. (7). Since the particle is positioned at the midpoint between the source and drain, \( C_L = C_R \) and then the total capacitance becomes twice of Eq. (7), i.e. \( C(r) = 2C_{\text{sphere}}(r) \). For small displacement in comparison with radius, i.e. \( |u_r| \ll a \), \( C(r) \) is approximated as

\[
\frac{1}{C(r)} \approx (1 - \beta \frac{u_r}{a}) \frac{1}{C_0},
\]

(8)

where \( C_0 = C(a) \) and the factor \( \beta \) is defined by

\[
\beta = 1 + \frac{a}{2c}.
\]

(9)

It is known that the intrinsic capacitance of a substance with finite volume is a minimum for a sphere\(^{27} \). Then the change in the intrinsic capacitance for the oblong modes depends on \( u_r \), and the change in the capacitance is mainly due to the change in the gaps between the island and electrodes. Considering only the change in \( \alpha \) in Eq. (7), we obtain

\[
\beta = \frac{a}{2c},
\]

(10)

where we suppose that the sphere is stretched toward the electrodes and regard \( u_r \) as the surface displacement in the direction. The magnitude Eq. (10) is not only for the oblong modes but also common to all the spheroidal modes except for the breathing mode. Using Eq. (7), the charging energy associated with phonons is separated from others in \( H_D \) as

\[
H_D \approx \sum_k \left( \varepsilon_{D,k} + \frac{eV}{2} \right) c_{D,k}^{\dagger}c_{D,k} + \frac{e^2}{2C_0} \left( \sum_k c_{D,k}^{\dagger}c_{D,k} \right)^2 - \beta \frac{u_r}{a} \frac{e^2}{2C_0} \left( \sum_k c_{D,k}^{\dagger}c_{D,k} \right)^2.
\]

(11)

\( \beta \) stands for a coupling constant between phonons and electrons, and then the breathing mode phonons are expected to play an dominant role in electron transport in comparison with other modes. On the other hand, the oblong mode has largest amplitude as compared with other modes as shown in the Appendix A, which is also expected to affect predominantly transport properties via the modulation of tunnel resistances. Hence we are devoted to the breathing and oblong vibration modes, hereafter.

Using an isotropic elastic continuum model, we derive the breathing mode (B) and its vibrational spectra in the gold spherical particle with free surface in Appendix A. The lowest angular frequency \( \omega_3 \) becomes \( \omega_3 = 9.52 \times 10^3/a \) rad.
s$^{-1}$, and higher frequencies are approximately harmonics of $\omega_B$, i.e. $\omega_n \approx n\omega_B$ ($n = 2, 3, \ldots$). The displacement at the particle surface becomes largest for $\omega_B$ and decreases for $\omega_n$ with increasing $n$. For $a = 1$ nm, the fundamental frequency becomes $\omega_B/2\pi = 1.52$ THz, and higher phonon frequencies become comparable to or larger than the Debye frequency (3.44 THz). In the frequency region, the elastic continuum model is not suitable to describe vibrations in the solid, and then the obtained phonon frequencies are unreliable except for the fundamental one. The fundamental frequency of the oblong mode of phonons in the island is $\omega_O = 3.24 \times 10^4$ rad·s$^{-1}$ and the higher modes are approximately harmonics of $\omega_O$. The amplitude of the fundamental frequency is largest among others, and then we expect that the oblong mode phonons at the fundamental frequency affect noticeably the transport in the SET. Considering these, we take account of only the breathing mode phonons at $\omega_B$ and the oblong mode phonons at $\omega_O$ in this work.

The surface displacement $u_r$ toward the electrodes is expressed in a quantized form by

$$u_r = \kappa_K (b_K + b_K^+),$$

(12)

in terms of the annihilation $b_K$ and creation operators $b_K^+$ of a breathing ($K = B$) and oblong mode phonons ($K = O$). In Eq. (12), $\kappa_K$ is the ratio of the surface displacement to $a$, which is evaluated as [Eq. (A25)]

$$\kappa_B = 2.33 \times 10^{-22} \frac{1}{a^2}$$

(13)

for the breathing mode at $\omega_B$, and

$$\kappa_O = 29.87 \times 10^{-22} \frac{1}{a^2}$$

(14)

for the oblong mode at $\omega_O$. Substituting Eq. (12) into Eqs. (11), we have $H_D$.

The Hamiltonian $H_{ph}$ of phonons in the island is

$$H_{ph} = \sum_j \hbar \omega_j \left( b_j^+ b_j + \frac{1}{2} \right),$$

(15)

where $J$ stands for a set of quantum numbers given in Eq. (A17). The heat bath $H_b$ is modeled by a phonon bath, and we assume linear coupling between the phonons in the island and those in the heat bath for $H_{ph,b}$.

We do not take into account the bulk electron-phonon interaction in the island and anharmonic interaction among phonons since they do not contribute to electron tunneling. However, they work for thermal equilibration in the island, whose effects are incorporated below.

### III. CANONICAL TRANSFORMATION

We assort the Hamiltonians into those of the system $H_S$, environment $H_E$ and interaction $H_{int}$:

$$H_S = H_D + H_{ph}$$

(16)

$$H_E = H_L + H_R + H_b$$

(17)

$$H_{int} = H_T + H_{ph-b}.$$  

(18)

Dealing with $H_{int}$ as perturbation, we diagonalize $H_S + H_E$ by a canonical transform, and modify $H_{int}$ by the same canonical transformation. In the rest of this work, we investigate individually the phonon effects of the breathing and oblong mode phonons, and then $b_K$ and $b_K^+$ appeared in Eq. (11) are the operators for either mode of them.

We separate the off-diagonal part $H_1$ containing $u_r$ in Eq. (11) from $H_S$ as

$$H_S = H_0 + \eta H_1,$$

(19)

where

$$H_0 = \sum_j \hbar \omega_j \left( b_j^+ b_j + \frac{1}{2} \right) + \sum_k \left( \varepsilon_{D,k} + \frac{eV}{2} \right) c_{D,k}^+ c_{D,k} + \mathcal{E}_C \left( \sum_k c_{D,k}^+ c_{D,k} \right)^2$$

(20)

$$H_1 = -(b_K + b_K^+) \mathcal{E}_C \left( \sum_k c_{D,k}^+ c_{D,k} \right)^2$$

(21)

$$\eta = \beta \kappa_K.$$  

(22)
Here $E_C$ reads

$$E_C = \frac{e^2}{2C_0}. \quad (23)$$

Suitably choosing an operator $S$ as

$$S = \frac{E_C}{\hbar \omega_K} (b_K - b_K^\dagger) \left( \sum_k c_{D,k}^\dagger c_{D,k} \right)^2, \quad (24)$$

we diagonalize $H_S$ as follows;

$$\tilde{H}_S = e^{\eta S} H_S e^{-\eta S} = \sum_J \hbar \omega_J \left( b_J^\dagger b_J + \frac{1}{2} \right) + \sum_k \left( \varepsilon_{D,k} + \frac{eV}{2} \right) c_{D,k}^\dagger c_{D,k} + \mathcal{E}_C \left( \sum_k c_{D,k}^\dagger c_{D,k} \right)^2 - \eta^2 \frac{E_C^2}{\hbar \omega_K} \left( \sum_k c_{D,k}^\dagger c_{D,k} \right)^4. \quad (25)$$

The eigenstate is given by $|\tilde{\Psi}_S\rangle = |\{n_{D,k}\}, \{m_J\}\rangle$, and the eigenenergy becomes

$$E_S = \sum_J \hbar \omega_J \left( m_J + \frac{1}{2} \right) + \sum_k \left( \varepsilon_{D,k} + \frac{eV}{2} \right) n_{D,k} + \mathcal{E}_S(n), \quad (26)$$

where $n_{D,k}$ is the occupation number of $k$-state in the island, and $m_J$ is the number of phonons of mode $J$. $n$ is the total number of extra electrons on the island with respect to the electrically neutral state. The charging energy $\mathcal{E}_S(n)$ given by

$$\mathcal{E}_S(n) = \mathcal{E}_C n^2 - \eta^2 \frac{E_C^2}{\hbar \omega_K} n^4, \quad (27)$$

where the second term in the right hand side of Eq. (27) is due to virtual phonons.

In contrast to $H_S$, $S$ commutes $H_E$;

$$[S, H_E] = 0, \quad (28)$$

and then $H_E$ is unchanged for the canonical transform. Then the eigenstate of the $\tilde{H}_S + H_E$ becomes

$$|\tilde{\Psi}\rangle = |\{n_{D,k}\}, \{m_J\}\rangle \otimes |\{n_{L,k}\}, \{n_{R,k}\}, \{m_\mu\}\rangle. \quad (29)$$

$n_{L,k}$, $n_{R,k}$ and $m_\mu$ are the occupation numbers of electrons in the source and drain, and the number of phonons of mode $\mu$ in the heat bath.

The tunnel Hamiltonian $H_T$ is converted in the same way as $H_S$, and becomes

$$\tilde{H}_T = \sum_{k,k'} \left[ t_{L,k}^0 c_{L,k}^\dagger c_{D,k'} B + t_{L,k}^0 B^\dagger c_{L,k'}^\dagger c_{D,k} + t_{R,k}^0 c_{R,k}^\dagger c_{D,k'} B + t_{R,k}^0 B^\dagger c_{R,k'}^\dagger c_{D,k} \right], \quad (30)$$

where

$$B = e^{\kappa K (\frac{\beta}{2} + 2k_\mu)} h_K^\dagger + e^{-\kappa K (\frac{\beta}{2} + 2k_\mu)} h_K. \quad (31)$$

IV. MASTER EQUATION

In order to formulate transport properties such as current and its noise, we introduce a reduced density matrix defined by $\rho_{nm}^{\text{red}}(t) = \text{Tr}[\rho(t)]_{n,m}$, where $m(=m_K)$ is the number of breathing/oblong mode phonons in the island.
The changes in the chemical potentials are related to the bias voltage as follows; Using a von Neumann equation, the master equation yields

\[
\rho_{00}^{nm} = \sum_{m'} \Gamma(0,m|0,m')\rho_{00}^{m'm'} + \sum_{m'} \Gamma(0,m|1,m')\rho_{11}^{m'm'}
\]

\[
\rho_{11}^{nm} = \sum_{m'} \Gamma(1,m|0,m')\rho_{00}^{m'm'} + \sum_{m'} \Gamma(1,m|1,m')\rho_{11}^{m'm'}.
\]

The matrix elements are

\[
\Gamma(0,m|1,m') = \sum_{\alpha=L,R} \gamma_{\alpha} |m\rangle |B| m'\rangle \langle m'| B\rangle |m\rangle \langle m'| \left( \frac{C_0}{e^2} \right) F(-\Delta\mu_\alpha + \varepsilon_C + \Delta\mu_D + (m' - m)\hbar\omega_K)
\]

\[
\Gamma(1,m|0,m') = \sum_{\alpha=L,R} \gamma_{\alpha} |m'\rangle |B| m\rangle \langle m| B\rangle |m'\rangle \left( \frac{C_0}{e^2} \right) F(\Delta\mu_\alpha - \varepsilon_C - \Delta\mu_D - (m - m')\hbar\omega_K)
\]

\[
\Gamma(0,m|0,m') = -\delta_{m,m'} \sum_{m''} \Gamma(1,m''|0,m) - 2\gamma_\infty N(\omega_K)[(m + 1)\delta_{m,m'} - m\delta_{m-1,m'}]
\]

\[
-2\gamma_\infty N(\omega_K) + 1][m\delta_{m,m'} - (m + 1)\delta_{m+1,m'}]
\]

\[
\Gamma(1,m|1,m') = -\delta_{m,m'} \sum_{m''} \Gamma(0,m''|1,m) - 2\gamma_\infty N(\omega_K)[(m + 1)\delta_{m,m'} - m\delta_{m-1,m'}]
\]

\[
-2\gamma_\infty N(\omega_K) + 1][m\delta_{m,m'} - (m + 1)\delta_{m+1,m'}]
\]

where

\[
\gamma_{\alpha} = (R_\alpha C_0)^{-1},
\]

and \( F(x) \) is

\[
F(x) = \frac{x}{1 - e^{-x/k_BT}}.
\]

Here we put

\[
\varepsilon_S(1) \approx \varepsilon_C,
\]

The changes in the chemical potentials are related to the bias voltage as follows;

\[
\Delta\mu_L = eV
\]

\[
\Delta\mu_R = 0
\]

\[
\Delta\mu_D = \frac{1}{2} eV.
\]

The Franck-Condon factor can be computed as

\[
|\langle m| B| m'\rangle|^2 = |\langle m| e^{z_1 z_{\bar{m}} - z_2 z_{\bar{m}'}} |m'\rangle|^2
\]

\[
e^{-z_1 z_2 z^2[m-m']^2/2} \left[ L_p^{|m-m'|}(z_1 z_2) \right]^2,
\]

where

\[
z = z_1 \Theta(m - m') - z_2 \Theta(m' - m)
\]

and

\[
z_1 = \kappa_K \left( \beta \frac{\varepsilon_C}{\hbar\omega_K} + \frac{a}{\lambda} \right)
\]

\[
z_2 = \kappa_K \left( \beta \frac{\varepsilon_C}{\hbar\omega_K} - \frac{a}{\lambda} \right).
\]
\[ p = \min(m, m') \quad \text{and} \quad q = \max(m, m'), \quad \text{and} \quad L_p^{\mid m-m'\mid} \] is the associated Laguerre polynomial. The diagonal elements of Eq. (44) decay from unity as the product \( z_1 z_2 \) increases from 0. On the other hand, the off-diagonal ones related to tunneling associated with multi-phonon emission or absorption increase.

Equations (32) and (33) comprise the terms of electron tunneling with or without phonon mediation and the phonon exchange terms with the heat bath in the Lindblad form\(^28\) as seen in Eqs. (36) and (37), where \( N(\omega_K) \) is the Bose-Einstein distribution function of phonons in the heat bath at the same frequency as the breathing or oblong mode phonons.

It is convenient to introduce \( \sigma_{mn}^{nm} \) for evaluation of noise properties in the SET\(^29\), which is subject to the following equation of motion;

\[
\dot{\rho}_{mm} = \sum_{m'} \Gamma(0, m|0, m') \rho_{m'm'}^{m'm'} + \sum_{m'} \Gamma(0, m|1, m') \rho_{m'm'}^{m'm'} + \sum_{m'} \Gamma(1, m|0, m') \rho_{m'm'}^{m'm'} + \sum_{m'} \Gamma(1, m|1, m') \rho_{m'm'}^{m'm'},
\]

(46)

with the initial condition \( \sigma_{mn}^{nm}(t = 0) = 0 \) for \( n = 0, 1 \) and \( m \geq 0 \).

We formulate the total charge transferred to the drain within time interval \( t \), using \( \sigma_{nn}^{mn} \), as

\[
\langle Q(t) \rangle = -e \sum_{n,m} \sigma_{nn}^{mn},
\]

(48)

and then the current \( I \) yields

\[
I = -\lim_{t \to \infty} \frac{\langle Q(t) \rangle}{t}.
\]

(49)

The noise power spectrum \( S(0) \) at zero frequency is related to the variance of \( Q \) as

\[
S(0) = \lim_{t \to \infty} \frac{2}{I} \Delta Q^2(t),
\]

(50)

and the time derivative of the variance is given in terms of \( \rho_{mn}^{nm} \) and \( \sigma_{nn}^{mn} \) by

\[
\frac{d}{dt} \Delta Q^2 = 2e^2 \sum_{m,m'} \Gamma(0, m|1, m') \sigma_{m'm'}^{m'm'} - e \langle \dot{Q} \rangle - 2\langle Q \rangle \langle \dot{Q} \rangle,
\]

(51)

where

\[
\langle \dot{Q} \rangle = -e \sum_{m,m'} \Gamma(0, m|1, m') \rho_{m'm'}^{m'm'}.
\]

(52)

The Fano factor is defined by

\[
F = \frac{S(0)}{2eI},
\]

(53)

using \( S(0) \) obtained from Eq. (51).

V. NUMERICAL RESULTS

A. Temperature in the particle

Phonon emission and absorption induced by electron tunneling are expected to heat up or to cool down the island. The temperature in the island is determined from the distribution of phonon occupation number. Then we first examine the distribution of phonon occupation number, and obtain the island temperature. Considering the particle is put at the midpoint between the electrodes, we put both the characteristic tunneling rates \( \gamma_L \) and \( \gamma_R \) to be \( \gamma \), and assume \( \omega_K \gg \gamma \). At the steady state, i.e. \( \dot{\rho}_{mn} = 0 \), thermal properties depend on the ratio \( \frac{\omega_K}{\gamma} \). Then we numerically investigate thermal and transport properties, putting \( \omega_K = 0.01 \gamma \) in this work for convenience. We solve Eqs. (32) and (33) self-consistently by means of the Runge-Kutta method of fourth order, where we substitute the temperature...
Breathing mode | Oblong mode
---|---
$\omega/2\pi$ | 1.516 THz | 0.515 THz
$\kappa_K$ | $2.426 \times 10^{-4}$ | $29.876 \times 10^{-4}$
\(\beta\) | $1 + \frac{eV}{V_C^0} = 1.5$ | $\frac{eV}{V_C^0} = 0.5$
$z_1$ | $1.62 \times 10^{-2}$ | $1.97 \times 10^{-1}$
$z_2$ | $6.517 \times 10^{-3}$ | $7.750 \times 10^{-2}$

| TABLE I: Parameters used in the numerical evaluation for $a = 1$nm. |

$T$ in Eq. (39) by the temperature in the island calculated from the averaged number of phonons discussed below in order to incorporate thermal equilibration among phonons and electrons. Here the bias voltage $V$ is expressed in unit of $e/C_0$, and $V_C^0/e = 1$ that is equivalent to $\frac{1}{2}eV = E_C$ is the threshold bias voltage for tunneling without phonon mediation. Used parameters are given in Table I.

We examined $\rho_{mm}^m$ versus $m$ at $T = 4$ K for various bias voltages from $V_C^0/e = 0.97$ to 1.2, and find $\rho_{mm}^m \propto \rho_{mm}^{00}$. Figure 2 plots the total phonon occupation probability $\rho_{mm}^m (= \rho_{mm}^{00} + \rho_{mm}^{11})$ versus $m$. $\rho_{mm}^m$ for $V_C^0/e \leq 0.97$ or $V_C^0/e \geq 1.20$ decreases exponentially with increasing $m$, indicating that $\rho_{mm}^m$ becomes a distribution of a thermal equilibrium state, i.e. the canonical distribution $\rho_{mm}^m = e^{-\frac{\hbar\omega_O}{k_B} \left(1 - e^{-\frac{\hbar\omega_O}{k_B} k_B T'}\right)}$, although the temperature $T'$ in the island is different from that of the environment when phonon mediated tunneling occurs. Using the Bose-Einstein distribution function, we estimate the temperature $T'$ from the averaged number of phonons $\langle m_O \rangle = Tr(m \rho_{nn}^{mm})_{K=0}$ in the island as

$$T' = \frac{\hbar \omega_O}{k_B} \ln \left(\frac{1}{\langle m_O \rangle + 1}\right).$$

(54)

$T'$ for $V_C^0/e \leq 0.97$ agrees with the heat bath temperature, i.e. 4 K, and $T'$ for $V_C^0/e \geq 1.2$ becomes larger than 4 K, which will be shown below.

The phonon occupation probability does not always become the canonical distribution, however. Figure 2 shows concave variation of $\rho_{mm}^m$ in the semi-log scale with respect to $m$ for $0.97 < V_C^0/e < 1.2$, manifesting deviation from the canonical distribution. Such deviation of phonon distribution probability from the canonical distribution is also known to take place in a molecular transistor, where electron tunneling mediated by multi-phonon absorp-
tion/emission occurs. Indeed, when the multi-phonon absorption/emission processes are artificially suppressed in the present work, the phonon occupation probability becomes the canonical distribution.

The effects of multi-phonon processes on $\rho^{mm}$ do not appear at $V C_0/e \leq 0.97$, as mentioned above. In the low bias voltage region, tunneling does not take place, and then the phonon distribution is governed by thermal energy exchange between the island and the heat bath, with the distribution becoming the canonical distribution at the heat bath temperature. In the bias voltage region $0.97 < V C_0/e < 1.2$, not only the phonon-absorbed tunneling but also the tunneling associated with phonon emission are possible, even when the bias is below the threshold voltage for phonon emission because of thermal fluctuations in electron energy. These processes affect the distribution of phonon occupation probability; according to the Monte Carlo simulations based on the master equations (32) and (33), for example, at $V C_0/e = 0.99$, tunneling associated with single-phonon emission occurs most frequently when an electron leaves the island, aside from tunneling without phonon mediation. Single-phonon absorption when an electron tunnels onto the island, and two-phonon emission when an electron tunnels off the island occur at a comparable rate, which is an order of magnitude smaller than the single-phonon emission. Thus the tunneling associated with multi-phonon emission makes the probability of multi-phonon states larger, so that the distribution deviates from the canonical distribution. Phonon-absorbed tunneling might be expected to lead to thermal cooling of the island in the bias region, but the tunneling associated with single phonon absorption is overcome by the tunneling with two-phonon emission as mentioned above. As a consequence, the island gains rather than loses energy. Even if the cooling takes place, the coupling to the thermal bath makes the effect small. At a larger bias voltage, $V C_0/e > 1.2$, the number of phonons in the island increases and then the exchange of phonons between the island and the heat bath dominates thermal equilibration. As a consequence, the phonon occupation probability becomes a canonical distribution at temperature larger than that of the heat bath. From these discussions, it is concluded that the canonical distribution appears when the thermal coupling between the island and the heat bath dominates thermal equilibration. At high heat bath temperature, $N(\omega_K)$ in the heat bath becomes large, enhancing thermal coupling between the island and the heat bath. The canonical distribution of $\rho^{mm}$ appears at e.g. 40 K, even in the bias region $0.97 < V C_0/e < 1.2$. The same effects appear for large thermal coupling $\gamma_\infty$, since it increases phonon energy exchange between the island and the heat bath.

![Graph](image)

**FIG. 3:** The temperature $T'$ in the nanoparticle versus $V$ at $T = 4$ K for $\gamma_\infty = 0.01\gamma$, $0.1\gamma$ and $0.5\gamma$. The data lines of $\gamma_\infty = 0.1\gamma$ and $0.5\gamma$ are denoted by arrows. $T$ is the temperature of the heat bath.

Because of the phonon occupation probability distinct from the canonical distribution, we define the temperature $T'$ in the island by means of entropy $S$ given by

$$S = -k_B \sum_m \rho^{mm} \log \rho^{mm}. \tag{55}$$
Numerically differentiating \( S \) and \( \langle m_K \rangle \) with respect to \( \{ \rho^{mm} \} \) provided that \( \sum_m \delta \rho^{mm} = 0 \) and using the following thermodynamic definition of temperature:

\[
\frac{1}{T'} = \frac{1}{\hbar \omega_K} \frac{dS}{d\langle m_K \rangle},
\]

(56)

\( T' \) is obtained. The resultant \( T' \) agrees well with the temperature given by Eq. (54). The dashed lines in Fig. 2 denote \( e^{-\hbar \omega_O/k_B T'} \) for \( VC_0/e = 1.00 \) and 1.05, which agree with \( \rho^{oo}_{0m} \) for \( m = 1 \) and 2, respectively.

In Fig. 3, we plot \( T' \) versus \( V \) at \( T = 4 \) K and 40 K for each case of the breathing and oblong mode phonons, with \( \gamma_{\infty} = 0.01\gamma, \ 0.1\gamma \) and \( 0.5\gamma \). The rate at which \( T' \) increases with bias depends on how fast the phonon energy dissipates to the heat bath, and becomes small for large \( \gamma_{\infty}/\gamma \).

The onset of the temperature increase depends on the phonon modes. The temperature rise begins at a lower bias voltage for the breathing mode than that for the oblong mode because the threshold voltage associated with phonon absorption is lower for the breathing mode; \( \omega_N > \omega_O \). Even below the threshold bias for tunneling associated with phonon emission, the island gains phonon energy by phonon emission as mentioned above. As a consequence, the temperature for the breathing mode rises more steeply at lower bias voltage. Conversely, the increasing rate is larger for the oblong mode than that for the breathing mode, which is seen clearly at the heat bath temperature of \( T = 40 \) K.

### B. Current, Differential Conductance and Noise

We plot the total current \( I \) and the current \( I_{ph} \) only due to phonon mediated electron tunneling versus \( V \) at \( T = 4 \) K in Fig. 4. Figure 4(a) shows the results for the breathing mode. The total current \( I \) begins to flow at \( VC_0/e = 1 \) and increases almost linearly with increasing \( V \). On the other hand, \( I_{ph} \) at \( VC_0/e = 1.00 \) \( \approx 1.03 \) is the threshold bias voltage for tunneling associated with single phonon emission. Because \( I_{ph} \) begins to rise at \( VC_0/e = 1.00 \), and increases nonlinearly with respect to \( V \). Although \( I_{ph} \) is three orders of magnitude larger than that for the breathing mode, it is not yet large enough to cause apparent modifications on the total current \( I \).

In order to resolve the subtle phonon effects on the current, we look at the differential conductance \( \sigma \) of the total current, the Fano factor \( F \), and \( \sigma_{ph} \) only due to phonon mediated tunneling. We expect steps in \( \sigma \) due to additional conductance channels arising from phonon emission. As for the Fano factor, a drastic increase in \( F \) is anticipated when the phonon mediated tunneling begins to occur in addition to the tunneling without phonon mediation. Figure 5 plots \( \sigma, \sigma_{ph} \) and \( F \) at 4 K for (a) the breathing and (b) the oblong modes, which show no notable changes in \( \sigma \) and \( F \), contrary to the expectation for both cases.

There is a prominent difference in the bias voltage dependence of \( \sigma_{ph} \) between the two cases; \( \sigma_{ph} \) for the breathing mode decays gradually with increasing bias after the abrupt increase in magnitude, similarly to \( \sigma \). The similarity indicates that \( I_{ph} \) is dominantly owing to a single channel, i.e. tunneling associated with single-phonon emission. In contrast, \( \sigma_{ph} \) for the oblong mode phonons continues to increase with increasing the bias, reflecting the nonlinear increase in \( I_{ph} \) with respect to the bias. Considering that the multi-phonon mediated tunneling makes the phonon number probability of the oblong mode deviate from the canonical distribution more than that of the breathing mode and that \( I_{ph} \) for the oblong mode is three orders of magnitude larger than that for the breathing mode, we speculate that \( I_{ph} \) for the oblong mode results from superposition of currents owing to multi-phonon mediated tunneling while \( I_{ph} \) for the breathing mode phonons is due to tunneling associated with single phonon emission. If so, characteristic steps in \( \sigma_{ph} \) are expected in Fig. 5(b), although \( \sigma_{ph} \) varies smoothly with increasing \( V \).

To illustrate the contribution of multi-phonon mediated tunneling to the transport, we investigate the second derivative of current with respect to \( V \). Figure 6(a) shows \( \frac{d^2 I}{dV^2} \) and \( \frac{d^2 I_{ph}}{dV^2} \) versus \( V \) for the breathing mode at various heat bath temperatures from 4 K to 40 K. \( \frac{d^2 I}{dV^2} \) is dominated by phonon absorption at \( V C_0/e = 1 \), which lowers and broadens with increasing temperature. The other hand, at \( T = 4 \) K, \( \frac{d^2 I_{ph}}{dV^2} \) shows sidebands at \( V C_0/e = 1 \pm 0.03 \) due to single phonon absorption (-) and emission (+). These two peaks are too small to be resolved in \( \frac{d^2 I}{dV^2} \). As the temperature increases, the peak due to the phonon absorption becomes larger and broadens, while the peak due to phonon emission flattens. The peaks eventually merge at \( T \geq 20 \) K, and the effects of phonon absorption and emission become indistinguishable above 20 K.

Figure 6(b) plots \( \frac{d^2 I}{dV^2} \) and \( \frac{d^2 I_{ph}}{dV^2} \) versus \( V \) for the oblong mode, and there are sidebands in \( \frac{d^2 I_{ph}}{dV^2} \) indicating single phonon absorption and emission at \( V C_0/e = 1 \pm 0.01 \). Because the two sidebands are close in energy, the peak corresponding to phonon absorption is only just resolved at low temperature. The two peaks merge with increasing temperature, and become undistinguishable at \( T = 20 \) K. Although we expected other sidebands associated with
FIG. 4: The total current $I$ and phonon mediated current $I_{ph}$ for (a) the breathing and (b) oblong modes versus $V$ at $T = 4$ K.

multi-phonon absorption/emission at, for example, $VC_0/e = 1.00 \pm 0.02$, no evidence of extra peaks was found in $\frac{d^2I_{ph}}{dV^2}$, indicating that the nonlinear increase in $I_{ph}$ for the oblong mode is not primarily the result of multi-phonon mediated tunneling.

To investigate this situation, we consider the current in the steady state that may be described as

$$I = e \sum_m \left[ \Gamma(1, m|0, m) + \Gamma(1, m + 1|0, m) + \Gamma(1, m - 1|0, m) \right] \rho_{m0}^{mn}.$$  

which is derived from the master equations (32) and (33) provided that $\langle \dot{n} \rangle = 0$. The relevant phonon mediated component $I_{ph}$ is

$$I_{ph} = e \sum_m \left[ \Gamma(1, m + 1|0, m) + \Gamma(1, m - 1|0, m) \right] \rho_{00}^{mm}.$$  

The matrix elements for single-phonon mediated tunneling can be approximated as

$$\Gamma(1, m + 1|0, m) \approx (m + 1)\Gamma(1, 1|0, 0).$$
FIG. 5: The differential conductance $\sigma$ of the total current $I$ and $\sigma_{ph}$ of phonon mediated current $I_{ph}$ together with the Fano factor $F$ for (a) the breathing and (b) oblong modes versus $V$ at $T = 4$ K. $R_T$ is the tunnel resistance between the particle island and leads.

\[
\Gamma(1, m - 1|0, m) \approx m\Gamma(1, 0|0, 1),
\]

since $\frac{\omega}{\hbar} L_p(z)^2 \approx \frac{\omega}{\hbar}(p + 1)^2$ for small $z$ in Eq. (44). Expressing $\rho_{nm}^{mm}$ by the product of electronic part $\rho_{nn}$ and the canonical distribution:

\[
\rho_{nm}^{mm} = \rho_{nn} e^{-\hbar\omega_K/k_B T'} Z,
\]

where

\[
Z = \frac{1}{1 - e^{-\hbar\omega_K/k_B T'}}.
\]

$I_{ph}$ yields

\[
I_{ph} \approx e \sum_{m} (m + 1)\Gamma(1, 1|0, 0) + m\Gamma(1, 0|0, 1) \rho_{00}^{mm}.
\]
The $\Gamma$s increase linearly with respect to the bias, and the number of phonons $\langle m_K \rangle$ also increases with increasing bias because of phonon emission. As a consequence, if $\rho_{00}$ is almost constant the second term of Eq. (63) increases nonlinearly with increasing bias, resulting in the nonlinear increase in $I_{ph}$.

The magnitude in $\langle m_K \rangle$ depends on both the electron-phonon coupling and the thermal resistance between the island and heat bath. Hence, the nonlinear behavior depends on how rapidly $\langle m_K \rangle$ grows with bias. The difference in the bias dependence of $I_{ph}$ between the breathing and oblong modes can be estimated by considering the situation where the first term in Eq. (63) is equal to the size of the second term because of the increase in $\langle m_K \rangle$. In this case, from Eq. (63) $\langle m_K \rangle$ becomes equal to the ratio,

$$\langle m_K \rangle = \frac{\Gamma(1,1|0,0)\rho_{00}}{\Gamma(1,1|0,0) + \Gamma(1,0|0,1)\rho_{00}}.$$  \hspace{1cm} (64)

The right hand side of Eq. (64) becomes 0 at the threshold bias voltage for single-phonon emission, and saturates to
be 0.13 for the oblong mode and 0.11 for the breathing mode at very large bias (see Appendix B). Because saturation happens quickly, the ratio becomes $\approx 0.1$ even at $V C_0/e = 1.1$ where the nonlinear behavior of $I_{ph}$ is confirmed for the oblong mode in Fig. 4(b). Supposing $\langle m_K \rangle = 0.1$, the temperature $T_K$ of island for the breathing and oblong modes are estimated from Eq. (54), to be, $T_B = 30.4$ K and $T_O = 10.3$ K, respectively.

As shown in Fig. 3, the temperature of the island for the oblong mode becomes larger than 10 K at $V C_0/e > 1.1$. In contrast, the temperature for the breathing mode does not reach to 30 K in the bias region studied. This argument shows that as a result of the bias dependence of $\langle m_K \rangle$, $I_{ph}$ for the oblong mode increases nonlinearly, while that for the breathing mode increases linearly over the parameter range considered. The difference in $I_{ph}$ between the oblong and breathing modes also leads to the difference in the magnitude and bias dependence of $\frac{d^2 I_{ph}}{dV^2}$ at $V C_0/e > 1.04$, as seen in Figure 6(a) and (b).

From the discussion, we can assess the behavior of $\frac{d^2 I_{ph}}{dV^2}$ at $V C_0/e > 1.04$ for the oblong mode at large $\gamma_\infty$. The large $\gamma_\infty$ reduces $\langle m_O \rangle$, which is expected to lead to linear increase in $I_{ph}$ like the breathing mode. Figure 7 compares $\frac{d^2 I_{ph}}{dV^2}$ for the oblong mode versus $V$ between $\gamma_\infty = 0.01 \gamma$ and $0.5 \gamma$. $\frac{d^2 I_{ph}}{dV^2}$ for $\gamma_\infty = 0.5 \gamma$ becomes negative at $V C_0/e = 1.026$ similar to that of the breathing mode, confirming that the nonlinear increase in $I_{ph}$ is a thermal effect.

![Figure 7](image)

FIG. 7: The second differential conductance of the total current $\frac{d^2 I}{dV^2}$ and that of the phonon mediated current $\frac{d^2 I_{ph}}{dV^2}$ versus $V$ at 4 K for the oblong mode. The dotted and solid lines indicate the results for $\gamma_\infty = 0.01 \gamma$ and $0.5 \gamma$, respectively.

VI. SUMMARY AND CONCLUSION

We have discussed how phonons associated with the island of an SET influence the electron transport of the device. We have formulated the tunnel Hamiltonian to incorporate the changes in the capacitances and tunnel resistances caused by phonons. Based on this result, we set up the master equations for the density matrix and formulate the current, differential conductance and the Fano factor.

Applying the model to an ideal SET containing a spherical gold particle 1 nm in radius, we calculated the effects of the breathing and oblong mode phonons on the thermal properties of the island and on the electron transport. Phonon emission associated with tunneling raises the temperature in the island, and multi-phonon emission makes the phonon occupation number in the island deviate from the canonical distribution even at steady state in the bias region close to the tunneling threshold. The current through the SET is dominated by tunneling without phonon mediation, with the differential conductance and the Fano factor showing little noticeable change due to phonons.
The second derivative of the phonon mediated current exhibits peaks associated with single phonon absorption and emission similar to phonon signatures found by inelastic electron energy spectroscopy\(^2\) in other systems. In the system studied, peaks associated with multi-phonon emission are smeared. We conclude that the dominant effect of the dynamic deformation of the particle island induced by phonons is on the thermal properties of the island rather than the electronic properties of the SET. Only the molecular vibrations such as vibrons lead to the vivid signatures of the vibrations of the island on the transport\(^1\)–\(^8\).

Appendix A: Acoustic phonons in a particle

We illustrate acoustic phonon modes in the spherical particle with an isotropic elastic continuum model\textsuperscript{30,31}. It is shown that there are spheroidal and toroidal modes. Using the normal modes, we formulate the quantized surface displacement $u_r$, which appears in Eq. (6).

The elastic wave equation in the isotropic medium yields

$$\rho \ddot{u}(r, t) = (\lambda + 2\mu)\nabla \cdot [\nabla \cdot u(r, t)] - \mu \nabla \times [\nabla \times u(r, t)], \quad (A1)$$

where $\rho$, $\lambda$ and $\mu$ are the mass density and the Lamé coefficients, respectively. We formulate the displacement vector $u(r, t)$, using a scalar and two vector potentials as

$$u(r, t) = \nabla \phi_1 + \nabla \times \Phi_2 + \nabla \times \nabla \times \Phi_3. \quad (A2)$$

The first term in the right hand side of Eq. (A2) represents the longitudinal acoustic wave component, and the other two terms do those of perpendicularly polarized transverse waves. According to the spherical shape, we express the vector potentials in the spherical coordinates as

$$\Phi_\alpha = (r, 0, 0) \phi_\alpha, \quad (A3)$$

for $\alpha = 2$ and 3. Putting Eq. (A3) into (A2), we have the following scalar wave equation for each potential function $\phi_\alpha$;

$$\left(\nabla^2 - \frac{1}{c_\alpha^2} \frac{\partial^2}{\partial t^2}\right) \phi_\alpha = 0, \quad (A4)$$

where $c_\alpha$ is the sound velocity given by

$$c_\alpha^2 = [(\lambda + \mu)\delta_{\alpha,1} + \mu] / \rho. \quad (A5)$$

The potential functions $\phi_\alpha$’s are given, in the spherical coordinates, by

$$\phi_\alpha(r, t) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} A_{\alpha}^l m j_l(k_\alpha r)P_l^{[m]}(\cos \theta)e^{-im\phi}e^{-i\omega t}, \quad (A6)$$

where $j_l$ is the spherical Bessel function of $l$ th order, and the wavenumbers $k_\alpha$’s satisfy the following dispersion relations;

$$\omega = k_1c_1 = k_2c_2 = k_3c_3. \quad (A7)$$

$P_l^{[m]}$ is the associated Legendre polynomials, and $m$ is an integer within the region $-l \leq m \leq l$. $A_{\alpha}^l m$’s are the coefficients of the potential functions, which are determined below.

Applying the stress free condition on the particle surface, we obtain two types of phonon modes in the particle: spheroidal and toroidal\textsuperscript{30,31}. The former is composed of $\phi_1$ and $\Phi_3$, having the radial component of displacement, while the latter owing to $\Phi_2$ does not have the component. The eigenvalue equation for the spheroidal modes becomes for given $(l, m)$

$$2j_{l+1}(\xi) \frac{\xi}{\eta^2} \left\{1 + \frac{(l-1)(l+2)}{\eta} \left[\frac{j_{l+1}(\eta)}{j_l(\eta)} - \frac{l+1}{\eta}\right]\right\} + j_l(\xi) \left\{-\frac{1}{2} + \frac{(l-1)(2l+1)}{\eta^2} + \frac{1}{\eta} \left[1 - \frac{2(l-1)(l+2)}{\eta^2}\right] \frac{j_{l+1}(\eta)}{j_l(\eta)}\right\} = 0, \quad (A8)$$

where $\xi = k_1 a$ and $\eta = k_3 a$, respectively. There is the relation between $\xi$ and $\eta$ from Eq. (A7) as

$$\eta = \frac{c_1}{c_3} \xi, \quad (A9)$$

so that Eq. (A8) becomes the equation with respect to only $\xi$. Although Eq. (A8) gives the spectra of spheroidal modes for a couple of parameters $(l, m)$, Eq. (A8) is actually independent of $m$, and then the spheroidal modes are
degenerate by $2l + 1$. Hereafter we express an eigenvalue by $\xi_{l,n} (\equiv k_{1,l,n} a = \omega_{l,n}^S a/c_1)$ for a given $l$, where $n$ indicates the $n$th solution of Eq. (A8). Then, the spheroidal mode is formulated as

$$u_{l,m,n}^S(r, t) = A_{l,m,n}^\dagger \{ \nabla \left[ j_l(k_{1,l,n}r)P_l^m(\cos \theta)e^{-i\phi} \right] + \alpha(l, n) \nabla \times \nabla \times \left[ (r, 0, 0)j_l(k_{3,l,n}r)P_l^m(\cos \theta)e^{-i\phi} \right] \} e^{-i\omega_{l,n}^S t},$$

(A10)

where the coefficient $A_{l,m,n}^\dagger$ and $\alpha(l)$ are determined from the following normalization condition of the spheroidal mode

$$\int_V |u_{l,m,n}^S(r, t)|^2 dV = 1.$$

(A11)

The coefficients become

$$A_{l,m,n}^\dagger = \left[ \frac{K_1(l, n)}{K_{3,l,n}} + \frac{\alpha^2(l, n)(l+1)K_3(l, n)}{K_{3,l,n}} \right]^{-1/2} \left[ 2l(m)(m+1) \right]^{-1/2},$$

(A12)

$$I(l, m) = \frac{2(l+|m|)!}{(l-|m|)!(2l+1)!},$$

(A13)

$$K_1(l, n) = \int_0^{\xi_{l,n}} \left[ \frac{\partial}{\partial \xi} j_l(\xi) \right]^2 \xi^2 d\xi + l(l+1) \int_0^{\xi_{l,n}} j_l^2(\xi) d\xi,$$

(A14)

$$K_3(l, n) = \int_0^{\eta_{l,n}} \left[ \left( \frac{\partial}{\partial \xi} + \frac{1}{\xi} \right) j_l(\xi) \right]^2 \xi^2 d\xi + l(l+1) \int_0^{\eta_{l,n}} j_l^2(\xi) d\xi,$$

(A15)

and

$$\alpha(l, n) = \frac{2(l-1)j_l(\xi_{l,n}) - 2\xi_l,nj_{l+1}(\xi_{l,n})}{[\eta_{l,n}^2 - 2(l^2-1)j_l(\xi_{l,n}) - 2\eta_{l,n}j_{l+1}(\xi_{l,n})]}.$$

(A16)

The toroidal modes are obtained in the same way as the spheroidal modes. Using annihilation $a_{l,m,n}^Q$ and creation operators $a_{l,m,n}^Q \dagger$ of phonons, we formulate the phonon field as

$$u(r) = \sum_{Q=S,T} \sum_{l=0}^\infty \sum_{m=-l}^l \sum_{n=1}^\infty \left( \frac{\hbar}{2\mu_1^{Q,n}} \right)^{1/2} \left[ a_{l,m,n}^Q u_{l,m,n}^Q(r) + H.c. \right]$$

(A17)

in the Schrödinger picture, where $Q$ specifies the spheroidal (S) or toroidal modes (T). We note here that a set of quantum numbers $J$ represents $(Q, l, m, n)$ in the Hamiltonian $H_{ph}$ of phonons in the particle [Eq. (15)].

In this work, we pay special attention to breathing (B) and oblong (O) modes, belonging to the spheroidal modes. Putting $l = 0$ and $m = 0$, the spheroidal modes become the breathing modes with amplitude of azimuthal symmetric, showing breathing motion. The spheroidal modes for $l = 2$ and $m = 0$ exhibit oblong vibrations, whose vibration spectra contain the lowest vibration frequency among all the spheroidal modes.

The eigenvalue equation Eq. (A8) for the spheroidal modes reduce for the breathing mode to

$$4j_l(\xi) \frac{\xi}{\eta^2} - j_0(\xi) = 0.$$

(A18)

Solving numerically Eqs. (A8) and (A18), we obtain the eigenfrequencies. For gold, $\xi$ and $\eta$ are related by

$$\eta = 2.66\xi$$

(A19)

from the mass density $\rho = 19.3 \text{ g} \cdot \text{cm}^{-3}$ and sound velocities $c_1 = 3.24 \times 10^3 \text{ m} \cdot \text{s}^{-1}$ and $c_3 = 1.22 \times 10^3 \text{ m} \cdot \text{s}^{-1}$. Substituting Eq. (A19) into (A18), the eigenfrequencies $\{\xi_{0,n}\}$ are numerically obtained from Eq. (A18), which are shown in TABLE A.

The fundamental frequency $\omega_B$ becomes, for $a = 1 \text{ nm},$

$$\omega_B = 2\pi \times 1.52 \times 10^{12} \text{ rad} \cdot \text{s}^{-1}.$$

(A20)
and higher frequencies $\omega_n (n = 2, 3, \ldots)$ are found, from TABLE A, to be approximately harmonics of $\omega_B$:

$$\omega_n \approx n \omega_B. \quad (A21)$$

However, $\omega_n (n \geq 2)$ becomes comparable to or larger than the Debye frequency. In the frequency region, the elastic continuum model cannot describe the particle vibrations correctly, so that the obtained phonon frequencies $\{\omega_n\} (n \geq 2)$ become unreliable for the particle size. Table A also shows the spectra of oblong vibrational modes, whose fundamental eigenfrequency is the smallest among the all the spheroidal modes. Although the harmonics being lower than the Debye frequency are considered to be valid, we pay attention only to the breathing and oblong modes of fundamental frequency $\omega_B$ and $\omega_O$ in this work as representative modes.

The phonon field only due to the phonon mode of interest at $\omega_K (K = B, O)$ yields

$$u_K(r) = \left( \frac{\hbar}{2 \rho \omega_K} \right)^{1/2} u_K(r) \left( b_K + b_K^\dagger \right). \quad (A22)$$

For the breathing mode, $b_B \equiv a_{0,0,1}^S$ and $b_B^\dagger \equiv a_{0,0,1}^{0S}$. $u_B \equiv u_{0,0,1}(r)$ has only the radial component, which becomes

$$[u_{0,0,1}(a)]_r = \frac{0.435}{a^{3/2}}. \quad (A23)$$

For the oblong mode, $b_O \equiv a_{2,0,1}^S$ and $b_O^\dagger \equiv a_{2,0,1}^{0S}$. $u_O \equiv u_{2,0,1}(r)$ and the radial component varies as $\cos \theta$. The amplitude yields

$$[u_{2,0,1}(a)]_r = \frac{3.252}{a^{3/2}}, \quad (A24)$$

at $\theta = 0$.

Using the result, the ratio $\kappa_K$ of the surface displacement to the radius for the breathing mode becomes

$$\kappa_B = 2.331 \times 10^{-22} \frac{1}{a^2}, \quad (A25)$$

and that for the oblong mode

$$\kappa_O = 29.876 \times 10^{-22} \frac{1}{a^2}. \quad (A26)$$

Using $\kappa_K$, the displacement in the radial component $u_r$ at the surface, which appeared in Eq. (6), yields

$$u_r = \kappa_K a (b_K + b_K^\dagger). \quad (A27)$$

Here Eq. (A27) gives the surface amplitude at $\theta = 0$ for the oblong mode.

**Appendix B**

The following ratio between the two $\Gamma$s at low temperature is simplified as follows:

$$\frac{\Gamma(1,0|0,1)}{\Gamma(1,1|0,0)} \approx A_K \frac{F(\frac{eV}{e} - \varepsilon_C + \hbar \omega_K)}{F(\frac{eV}{e} - \varepsilon_C - \hbar \omega_K)}$$

$$\approx A_K \frac{\frac{eV}{e} - \varepsilon_C}{\frac{eV}{e} - 1 - \frac{\hbar \omega_K}{\varepsilon_C}} \quad (B1)$$

where

$$A_K = \left( \frac{z_1}{z_2} \right)^2. \quad (B2)$$

Putting Eq. (B1) into Eq. (64), the right hand side yields

$$\frac{\Gamma(1,1|0,0)}{\Gamma(1,1|0,0) + \Gamma(1,0|0,1)} = \frac{1}{1 + A_K \frac{\frac{eV}{e} - 1 + \frac{\hbar \omega_K}{\varepsilon_C}}{\frac{eV}{e} - 1 - \frac{\hbar \omega_K}{\varepsilon_C}}} \quad (B3)$$
In the bias region \( \frac{C_0 V}{e} > 1 + \frac{\hbar \omega K}{\varepsilon C} \), the magnitude varies from 0 to \( \frac{1}{1 + A_B} \) with increasing bias. The saturated magnitudes are 0.11 for the breathing mode and 0.13 for the oblong mode. Here the coefficients \( A_B \) and \( A_O \) are

\[
A_B = 8.03 \\
A_O = 6.46.
\]

Since the phonon energy is small in comparison with \( \varepsilon C \):

\[
\frac{\hbar \omega_B}{\varepsilon C} = 0.03 \quad (B6) \\
\frac{\hbar \omega_O}{\varepsilon C} = 0.01, \quad (B7)
\]

Eq. (B3) rapidly saturates, and becomes approximately 0.1 at \( V C_0/e = 1.1 \) where the nonlinear-dependence of \( I_{ph} \) is seen for the oblong mode in Fig. 4(b).
