Abstract: We experimentally demonstrate a two-color two-photon resonant excitation of the doubly excited 2p2 1S state in helium atoms by the combination of 19th and 21st harmonic photons of a Ti:sapphire laser. Production of the 2p2 1S state is confirmed by the experimental observation that the electron emission from this state does not depend on the direction of harmonic polarization. Our ab-initio theoretical results through the solution of time-dependent Schrödinger equation are consistent with the experimental results and confirm the first successful production of a doubly excited state by high-harmonic pulses.

1. Introduction

Development of ultrashort pulse lasers has led to the generation of coherent extreme-ultraviolet (XUV) and soft x-ray (SXR) light [1, 2]. Synchrotron orbital radiation (SOR) has been a unique light source in XUV and SXR spectroscopy for a long time and providing light with excellent spatial coherence. Indeed study on the relaxation and dissociation dynamics of atoms and molecules using a one-photon transition by SOR has been one of the main research issues in XUV linear spectroscopy. Although the usefulness of XUV nonlinear spectroscopy is rather obvious, to go beyond the linear region is not possible with SOR, since the available peak intensity is very limited due to the lack of temporal coherence. Alternative light sources in the XUV or SXR region are based on lasers: The highest photon energy of the high harmonics generated by ultrashort pulse lasers was extended to 1 keV and free-electron lasers (FELs) for the XUV region have been developed [3, 4]. Yet, the available intensity is not sufficient, and as a result, experimental investigation of nonlinear optics in the XUV or SXR region has been a rather uncharted territory so far.

Further development of high harmonics by femtosecond lasers has paved the way for XUV nonlinear optics in the last few years [5-10]: Two-photon ionization of helium atoms was demonstrated using the 9th harmonic of a Ti:sapphire (TiS) laser and applied to the autocorrelation measurements [5]. Moreover, above-threshold ionization (ATI) was also observed and attosecond pulses were characterized using the ATI process [9, 11, 12]. Note
that all these experiments are based on the non-resonant processes in that neither bound nor autoionizing states are resonantly involved during the ionization processes. If we are to use XUV pulses from the high harmonics for ultrafast nonlinear XUV spectroscopy, a two-photon resonant excitation to the final state of interest is greatly desired, since highly excited states of atoms and molecules, which have tens of eV state energy and cannot be reached by the one-photon process from the initial state due to the parity selection rule, will be within reach by the two-photon process.

Although the two-photon excitation to a doubly excited state with a FEL was suggested recently [4, 13], it was difficult to selectively excite a specific state, since the photon energy of the FEL was fixed to 38.5 eV. In contrast, high harmonics have multiples of the photon energy of the fundamental laser up to the cut-off energy [14], and not only one of the harmonics (one-color two-photon excitation) but a combination of the two (two-color two-photon excitation) may be used to resonantly excite the final state of interest. Moreover, the center energy of each harmonic can be shifted by changing the laser chirp. That is, use of the negatively and positively chirped laser pulses enables us to almost continuously shift (tune) the center photon energy upwards and downwards, respectively [15]. Because of this practical tunability of the photon energy, high harmonics are very useful for XUV and SXR nonlinear spectroscopy of atoms and molecules, etc. Toward this goal, experimental observation of two-photon resonant excitation of a doubly excited state by high-harmonic pulses would serve as a cornerstone for ultrafast XUV nonlinear spectroscopy.

In this paper, we report the first experimental observation of two-photon resonant excitation to the doubly excited state of helium atoms by XUV harmonic photons together with our ab-initio theoretical results. Here, we focus on the helium atom as a nonlinear optical medium, since it is the simplest three-body system consisting of an atomic nucleus and two electrons, which can be rigorously treated in the theoretical description. One of the interesting properties of helium atoms is the presence of doubly excited states [16-24, 13] All the doubly excited states of helium atoms are located far above the ionization threshold, and hence they autoionize. Although the doubly excited states of helium were first observed more than forty years ago using SOR [17], they are still under extensive investigation because helium is a prototype system with electron-electron correlations. Related to our work, optical excitation of the doubly excited states by XUV attosecond pulses [22, 24] has been theoretically studied recently.

Figure 1(a) shows the energy diagram of the relevant states of helium atom. In this paper we focus on the $2p^2\,^1S$ state, because the excitation energy is 62.1 eV and corresponds to the summed energy of the 19th and 21st harmonics. The $2p^2\,^1S$ state is known to decay into a $1s\,^1S$ continuum state through the autoionization with a lifetime of 140 fs [22], where the notation

![Energy Diagram of Helium Atom](image-url)
“εs” represents the electron in the s continuum with a kinetic energy of ε (>0). Therefore, if we are able to resonantly excite the 2p2 1S state by two-photon (19th and 21st harmonic) absorption, we should be able to confirm the process by detecting autoionizing electrons in the s wave at a kinetic energy of 37.4 eV. In order to confirm the successful detection of autoionizing εs electrons, we have measured the electron signals with two different polarization geometries, the detail of which will be explained later in this paper.

2. Experimental

The experimental setup for the two-photon excitation shown in Fig. 1b was as follows: 800-μJ, 30-fs TiS laser pulses at a repetition rate of 1 kHz were focused on a pulsed jet of argon gas; the gas nozzle was positioned after the laser focus so that we can attain a good phase matching for high harmonic generation [25]. The peak intensity for high-harmonic generation was 2.5 × 1014 W/cm2. The photon energies of high harmonics were adjusted by changing the amount and sign of the chirp through the pulse compressor of the TiS laser system. The 19th and 21st harmonics were separated from the fundamental laser by an Al filter and then focused into helium atoms by a concave Sc/Si multilayer mirror with a focal length of 5 cm. The center wavelength of this mirror was 42 nm with a 4-nm bandwidth. The kinetic energy of the ejected electrons was analyzed by a time-of-flight-type electron spectrometer with a magnetic-bottle to have a wide detection angle. We have applied an electric field to the flight tube to slow down the fast electrons, which results in the improvement of energy resolution. From the temporal widths of the electronic trigger pulses, the energy resolution of the detector around 37 eV was estimated to be 420 meV. As we have already mentioned and will explain more in detail later in this paper, light polarization is a very important parameter to confirm the resonant excitation to the doubly excited 2p2 1S state. Therefore, the direction of linear polarization of the high-harmonic pulses was rotated by the rotation of linear polarization of the fundamental laser beam with a half-wavelength plate. Since the εp electrons produced by one-photon ionization with high harmonics obey the cos2θ distribution law where θ is a polar angle between the polarization direction of the harmonics and the detection direction, we can estimate the collection angle of the electron detector by measuring the εp electrons for the two

![Diagram](https://latex.codecogs.com/png.latex?\text{Fig.~2.~Spectra~of~the~19th~and~21st~harmonics~of~a~TiS~laser~pulse~with~different~center~photon~energies.~The~hatched~areas~indicate~the~spectral~components~that~contribute~to~the~two-photon~excitation~to~the~2p^2~1S~state.})
polarization geometries, i.e., parallel and perpendicular linear polarization with respect to the detection direction. The intensity ratio of the $\epsilon p$ electrons signal for the parallel and perpendicular linear polarization geometries was found to be $3.0 \pm 0.1$, from which we estimated the collection polar angle as about 58 degrees. We accumulated the electron signal for 4 hours for each spectrum.

Figure 2 shows the spectra of the 19th and 21st harmonics used for the experiment. The hatched areas in the spectra indicate the spectral components which could, according to the law of energy conservation, presumably contribute to the resonant excitation of the $2p^2 1S$ state. Since the center energies of the spectra in Fig. 2(b) are slightly shifted to the lower energy than those in Fig. 2a, only 60% energy of the 19th harmonic is expected to participate in the two-photon excitation for the case of Fig. 2(b).

3. Observation of the doubly excited state

Using these high-harmonic pulses, the electron spectra of helium for the kinetic energy between 28 and 42 eV were measured and are shown in Figs. 3a and 3b with error bars which correspond to the harmonic spectra in Fig. 2a and 2b, respectively. In Figs. 3a and 3b the solid and broken lines represent the results for the parallel and perpendicular linear polarization geometries, respectively. Although the 37th to 41st harmonics are far out of the designed reflectance bandwidth of the Sc/Si mirror and must be already extremely weak at the target, the huge peaks by those harmonics appear in the spectra, since they originate from the one-photon processes. Nevertheless, the signal with a kinetic energy of about 37 eV, shown by the

![Image](image_url)
hatched area in Fig. 3(a), seems to originate from the two-photon resonant excitation of doubly excited \(2p^2 1S\) state, which must be confirmed. Here, the hatched area cannot come from the two-photon processes involving one harmonic (39th or 41st) photon and one fundamental photon. If that were the case, sidebands would have been appeared by the huge one-photon ionization peaks.

We have confirmed the excitation of the \(2p^2 1S\) state by two completely different experimental methods as we explain below: In the first confirmation method, we utilized the two different harmonic spectra shown in Figs. 2(a) and 2(b), and checked the change, if any, of the electron spectra shown in Figs. 3(a) and 3(b). As we have already mentioned, the excitation efficiency of the \(2p^2 1S\) should become smaller when we employ the harmonics with the spectra shown in Fig. 2b, because the spectral intensity that can participate to excite the \(2p^2 1S\) state was reduced to 60%. Consistent with this argument, the number of electrons with a kinetic energy of about 37 eV indeed decreased, as shown in Fig. 3(b). It is difficult, however, to quantitatively estimate the decrease because of the overlap of the relevant two-photon signal with the one-photon signal by the 39th and 41st harmonics. In the second confirmation method, we made use of the angle-dependence of the ejected electrons by the one- and two-photon processes. Since the \(2p^2 1S\) state necessarily decays into the \(1s\) continuum state through autoionization, the ejected electrons are the \(1s\) electrons with an isotropic spatial distribution upon ejection. This means that the two-photon resonant signal has no polarization dependence, which is indeed what we find in Fig. 3. In contrast, one-photon ionization results in the ejection of \(1p\) electrons which now obeys the \(\cos^2 \theta\) distribution law and hence exhibits polarization dependence for our finite detection angle (about 58 degrees as estimated before). This clearly shows that we have successfully demonstrated the two-photon resonant excitation of the doubly excited \(2p^2 1S\) state by harmonic photons.

4. Comparison with ab-initio theory

For further confirmation, we have also undertaken ab-initio theoretical calculations by solving the time-dependent Schrödinger equation (TDSE) for the helium atom with two active electrons [26, 27]. Briefly, the computational procedure can be summarized as follows: First, we construct the two-electron states of helium by diagonalizing the two-electron Hamiltonian with more than 7000 configurations for the S, P, and D symmetries in a spherical box of 1000 atomic units. Then, we expand the time-dependent two-electron wavefunction under the harmonic field as a superposition of two-electron states multiplied by time-dependent expansion coefficients. Thus, the TDSE is reduced to a set of first-order differential equations for the time-dependent expansion coefficients. The number of first-order differential equations we solve is 8000. As for the field, the harmonic field is assumed to contain two main components corresponding to the 19th and 21st harmonics, and three subsidiary components corresponding to the 37th, 39th, and 41st harmonics. However, as our experimental results in Figs. 2 and 3 indicate, photon energies of the subsidiary harmonics seem to have shifted since these harmonics are produced in the argon gas under the presence of lots of electrons due to ionization. To phenomenologically account for the shift, we have shifted the photon energies for the three subsidiary harmonic components. Thus the harmonic photon energies employed in the calculations are 29.45 eV and 32.5 eV for the main harmonics, and 55.48 eV, 59.31 eV, and 63.23 eV for the subsidiary harmonics, respectively. It is also very likely that the harmonics are negatively chirped, since they are produced under the presence of lots of electrons. To account for the possible chirp, the harmonic pulse is assumed to have a cosine-squared temporal envelope function with a 4 fs (FWHM) duration with a linear negative chirp [28], which has a spectral bandwidth of the transform-limited 2 fs pulse. The peak intensities employed in the calculations are 3.8x10^9 W/cm^2 and 1.2x10^9 W/cm^2, respectively, for the main (19th and 21st) harmonics, which were estimated from the experimentally measured pulse energies and the beam diameters. Because the pulse energies of the three subsidiary harmonics were too weak to measure, we temporarily assumed that they are approximately...
<10^{-6} of the 19th harmonic. In order to obtain the electron spectra comparable to the experimental ones, we have slightly scaled the one-photon peaks for each subsidiary harmonic component.

The solid and broken lines in Fig. 4(a) represent the calculated electron spectra associated with the two-photon absorption followed by the electron ejection into the $\varepsilon s$ and $\varepsilon d$ waves, respectively. For clarity, in Fig. 4a, we have omitted the electron signals originating from the one-photon processes by the subsidiary harmonics. Some of the distinct resonant peaks, such as $2s^2 \, 1S$ at 57.84 eV, $2p^2 \, 1D$ at 59.90 eV, $2p^2 \, 1S$ at 62.10 eV, and $2s3s \, 1S$ at 62.96 eV, are labeled in Fig. 4(a). To be more realistic, we now include the electron signals originating from the one-photon processes by the subsidiary harmonics, and applied a window function with a 420 meV width of the Gaussian function. After taking into account the anisotropic and isotropic spatial distribution of the electron ejection by the one- and two-photon ionization, respectively, the calculated results are shown in Fig. 4(b) for the parallel and perpendicular linear geometries. Because of the huge peaks induced by the 37th, 39th, and 41st subsidiary harmonics, some of the peaks associated with the two-photon processes shown in Fig. 4a are buried in Fig. 4b. Nevertheless, the peak associated with the resonant two-photon excitation of the doubly excited $2p^2 \, 1S$ state can be clearly seen in Fig. 4(b). This theoretical finding is quite consistent with the experimental results in Fig. 3(a), and again we have confirmed that the $2p^2 \, 1S$ state has been successfully excited through the two-photon resonant processes.

Fig. 4. (a) Calculated electron spectra through the two-photon excitation by the two main (19th and 21st) harmonics. The solid and broken lines represent the electron signal into the $\varepsilon s$ and $\varepsilon d$ waves, respectively. (b) Calculated electron spectra by the two main harmonics and three subsidiary (37th, 39th, and 41st) harmonics under the parallel (solid line) and perpendicular (broken line) linear polarization geometries. In Fig. 4b, detection angle and the energy resolution of the electron spectrometer have been taken into account.
5. Summary

In summary, we have experimentally demonstrated the two-color two-photon resonant excitation of the doubly excited $2p^2 \ ^1S$ state in helium by the combination of the 19th and 21st harmonics from the TiS laser. We have also performed the ab-initio theoretical calculations and found a good agreement with the experimental results. Our results can serve as a doorway toward *ultrafast XUV nonlinear spectroscopy* in that highly excited states of atoms and molecules, which have never been accessed by the one-photon process via SOR due to the parity selection rule, will become within reach by the two-photon process.
