Analysis of a Synchronously Mode-Locked and Internally Frequency-Doubled CW Dye Laser

Mikio Yamashita, Keita Yamada, and Takuzo Sato

Abstract—We present analytical studies of a synchronously mode-locked and internally frequency-doubled CW (SMLFD) dye laser. The analysis describes the cavity detuning behavior of the pulse duration and the square of its peak intensity (the signal intensity of the autocorrelation trace) in terms of system parameters for different lengths of the intracavity crystal. The results predict the broadening of the pulse duration with the increase of the crystal length even though the condition of the group velocity matching is satisfied. It is shown that the prediction is in good agreement with the experimental results of the SMLFD rhodamine 6G laser with an ADP crystal in the cavity. Furthermore, the variation of the minimum pulse duration at the optimum cavity length as a function of the harmonic conversion efficiency is derived.

Manuscript received June 8, 1981; revised August 25, 1981.

I. Introduction

Recently, a synchronously mode-locked and intracavity frequency-doubled CW (SMLFD) dye laser has been operated to produce efficiently continuous trains of UV picosecond pulses [1], [2], and employed for the study of fast photochemical reactions of molecules [3]. In the previous papers [1], [2], it has been briefly discussed that the broadening of the pulse duration of the fundamental wave is mainly due to the following two causes even though the condition of the group velocity matching is satisfied: one is the nonlinear losses due to the frequency-doubling process in the cavity and the linear insertion losses of a nonlinear crystal; the other is the limitation of the intracavity bandwidth due to the birefringent effect of the crystal. The subject of this paper is to analyze quantitatively the characteristics of such a SMLFD dye laser.
laser, where the effects of the intracavity crystal for second-harmonic generation (SHG) on the duration of the dye laser pulse are described in detail.

The pulse characteristics of the usual synchronously mode-locked CW (SML) dye laser were theoretically considered by some authors. Kim et al. [4] presented an analysis on the SML laser in the time domain by the self-consistent approach describing the steady-state pulse properties in terms of the system parameters. In the analysis it was shown that the pulse duration is determined by $\frac{1}{2}$ power of the duration of pumping pulses and inverse $\frac{2}{3}$ power of the bandwidth of a frequency tuning element. Ausschnitt et al. [5] also discussed analytically the effect of cavity length detuning by slightly modifying the Haus’ steady-state equation [6] for the dye pulse envelope. They showed that the pulse duration is proportional to $\frac{1}{2}$ power of the duration of pumping pulses and inverse $\frac{1}{3}$ of the bandwidth of the tuning element. The latter model, however, does not reproduce well the experimental result of the broadening of the pulse duration in the region where the cavity length is shorter than the optimum position [7]. Our analysis is performed with an extension of the former model so as to include the effects of the nonlinear losses due to the SHG process, the birefringent filter due to the intracavity SHG crystal, and the insertion losses of the crystal.

An intracavity SHG in a forced mode-locked Nd:YAG laser by a loss modulator was analyzed by Falk [8]. In the analysis it was quantitatively shown that the envelope of the electric field with fundamental frequency emerging from the SHG crystal suffers decrease in the amplitude and broadening in the pulse duration, while essentially maintaining the original pulse envelope. This result is applied to the effect of the SHG process on the dye pulse envelope in the SMLFD dye laser.

In the next section, the basic analytical model is briefly reviewed and fundamental equations describing the characteristics of the SMLFD dye laser are presented, while in Section III their solutions are derived. Section IV gives cavity detuning characteristics of the pulse duration and the square of its peak width of the tuning element. The notation used follows [4]: the small signal gain $g_0$ of the pulse intensity is equal to $[2 \ln 2/\gamma]^{1/2}$. The input signal to the active medium is amplified by the pumping pulse $\Delta \times (1/\sqrt{\pi \tau_p}) \times \exp \left(-\left(\frac{(t - \Delta t)/\tau_p}{2} \right)^2 \right)$ of the duration $2\sqrt{\ln 2} \tau_p$ and the pump energy $\Lambda$ absorbed in its medium per unit volume. The $\Delta t = 2(\tau_p - L_d/c)$ is the time lag between pump and dye peaks corresponding to the difference between pump $L_p$ and dye $L_d$ cavity-length. After passage through the medium, the pulse envelope becomes

$$V_i(t) = G(t) V_o(t)$$

(2)

by using the single-pass gain $G(t)$ [4]. The gain at the line center in the case where the duration of the pumping pulse is much longer than that of the dye pulse is expressed by

$$G(t) = \exp \left(g + \frac{\delta \gamma^2}{2} \right) \times \exp \left(-\left(\frac{t}{\tau_p}\right)^2 \right)$$

(3)

in terms of an effective gain factor

$$g = g_0 \times \text{erfc} \left(\frac{\Delta t}{\tau_p}\right) \times \exp \left(-\frac{1}{2\tau_p^2} \sqrt{\frac{\pi}{2\gamma}} \right)$$

(4)

a gain-modulation strength

$$\delta = \frac{2g_0}{\sqrt{\pi \tau_p}} \times \exp \left(-\frac{(\Delta t)^2}{\tau_p^2}\right) \times \exp \left(-\frac{1}{2\tau_p^2} \sqrt{\frac{\pi}{2\gamma}} \right) \times \frac{1}{\tau_p}$$

(5)

and an amount shifted in time of the modulation peak from the peak of the amplified pulse

$$\tau = \frac{1}{2} \left[T_s - \frac{1}{2} \sqrt{\pi \tau_p} \times \text{erfc} \left(\frac{\Delta t}{\tau_p}\right) \times \exp \left(\frac{(\Delta t)^2}{\tau_p^2}\right) \right]$$

(6)

The normalized envelope $V(t)$ of the electric field amplitude of the dye pulse is assumed to be Gaussian, and the propagation of its pulse is traced around the optical cavity shown schematically in Fig. 1. The effect of each optical component on the Gaussian pulse is considered, and it is required that pulse envelope repeats itself after a roundtrip traversal of the cavity.

The analysis makes the following assumptions: 1) for a homogeneously broadened two-level dye laser system, both pulse envelopes of the pumping ion laser and the dye laser are Gaussian; 2) the lifetime of the upper level of dye molecules is much longer than the duration $2\sqrt{\ln 2} \tau_p$ of the pumping pulse but is shorter than the cavity roundtrip time; 3) the gain profile is much broader than the pulse bandwidth; 4) the effect of the multiple pass through the frequency-doubling crystal is to alter the Gaussian pulse parameters such as the duration $\tau_p$ and the amplitude $V(t)$, while maintaining a Gaussian envelope. This is generally thought to be reasonable, since the practical conversion efficiency of SHG is less than one percent [8].

The temporal variation of the dye-pulse envelope at point 1 next to the laser medium in Fig. 1 is given by

$$V_0(t) = \exp \left(-\gamma t^2 \right)$$

(1)

where the duration $\tau_p$ of the pulse intensity is equal to $[2 \ln 2/\gamma]^{1/2}$. The input signal to the active medium is amplified by the pumping pulse $\Delta \times (1/\sqrt{\pi \tau_p}) \times \exp \left(-\left(\frac{(t - \Delta t)/\tau_p}{2} \right)^2 \right)$ of the duration $2\sqrt{\ln 2} \tau_p$ and the pump energy $\Lambda$ absorbed in its medium per unit volume. The $\Delta t = 2(\tau_p - L_d/c)$ is the time lag between pump and dye peaks corresponding to the difference between pump $L_p$ and dye $L_d$ cavity-length. After passage through the medium, the pulse envelope becomes

$$G(t) = \exp (g + \delta \gamma^2) \times \exp (-\gamma (t - \tau)^2)$$

(3)

in terms of an effective gain factor

$$g = g_0 \times \text{erfc} \left(\frac{\Delta t}{\tau_p}\right) \times \exp \left(-\frac{1}{2\tau_p^2} \sqrt{\frac{\pi}{2\gamma}} \right)$$

(4)

a gain-modulation strength

$$\delta = \frac{2g_0}{\sqrt{\pi \tau_p}} \times \exp \left(-\frac{(\Delta t)^2}{\tau_p^2}\right) \times \exp \left(-\frac{1}{2\tau_p^2} \sqrt{\frac{\pi}{2\gamma}} \right) \times \frac{1}{\tau_p}$$

(5)

and an amount shifted in time of the modulation peak from the peak of the amplified pulse

$$\tau = \frac{1}{2} \left[T_s - \frac{1}{2} \sqrt{\pi \tau_p} \times \text{erfc} \left(\frac{\Delta t}{\tau_p}\right) \times \exp \left(\frac{(\Delta t)^2}{\tau_p^2}\right) \right]$$

(6)

The normalized envelope $V(t)$ of the electric field amplitude of the dye pulse is assumed to be Gaussian, and the propagation of its pulse is traced around the optical cavity shown schematically in Fig. 1. The effect of each optical component on the Gaussian pulse is considered, and it is required that pulse envelope repeats itself after a roundtrip traversal of the cavity.

The analysis makes the following assumptions: 1) for a homogeneously broadened two-level dye laser system, both pulse envelopes of the pumping ion laser and the dye laser are Gaussian; 2) the lifetime of the upper level of dye molecules is much longer than the duration $2\sqrt{\ln 2} \tau_p$ of the pumping pulse but is shorter than the cavity roundtrip time; 3) the gain profile is much broader than the pulse bandwidth; 4) the effect of the multiple pass through the frequency-doubling crystal is to alter the Gaussian pulse parameters such as the duration $\tau_p$ and the amplitude $V(t)$, while maintaining a Gaussian envelope. This is generally thought to be reasonable, since the practical conversion efficiency of SHG is less than one percent [8].

The temporal variation of the dye-pulse envelope at point 1 next to the laser medium in Fig. 1 is given by

$$V_0(t) = \exp \left(-\gamma t^2 \right)$$

(1)

where the duration $\tau_p$ of the pulse intensity is equal to $[2 \ln 2/\gamma]^{1/2}$. The input signal to the active medium is amplified by the pumping pulse $\Delta \times (1/\sqrt{\pi \tau_p}) \times \exp \left(-\left(\frac{(t - \Delta t)/\tau_p}{2} \right)^2 \right)$ of the duration $2\sqrt{\ln 2} \tau_p$ and the pump energy $\Lambda$ absorbed in its medium per unit volume. The $\Delta t = 2(\tau_p - L_d/c)$ is the time lag between pump and dye peaks corresponding to the difference between pump $L_p$ and dye $L_d$ cavity-length. After passage through the medium, the pulse envelope becomes

$$G(t) = \exp (g + \delta \gamma^2) \times \exp (-\gamma (t - \tau)^2)$$

(3)

in terms of an effective gain factor

$$g = g_0 \times \text{erfc} \left(\frac{\Delta t}{\tau_p}\right) \times \exp \left(-\frac{1}{2\tau_p^2} \sqrt{\frac{\pi}{2\gamma}} \right)$$

(4)

a gain-modulation strength

$$\delta = \frac{2g_0}{\sqrt{\pi \tau_p}} \times \exp \left(-\frac{(\Delta t)^2}{\tau_p^2}\right) \times \exp \left(-\frac{1}{2\tau_p^2} \sqrt{\frac{\pi}{2\gamma}} \right) \times \frac{1}{\tau_p}$$

(5)

and an amount shifted in time of the modulation peak from the peak of the amplified pulse

$$\tau = \frac{1}{2} \left[T_s - \frac{1}{2} \sqrt{\pi \tau_p} \times \text{erfc} \left(\frac{\Delta t}{\tau_p}\right) \times \exp \left(\frac{(\Delta t)^2}{\tau_p^2}\right) \right]$$

(6)
The output pulse resulting from the passage is found by one application of the transfer function of the crystal [8]:

\[ V_2(t) = A_1 \exp \left( -\gamma_1 (t + t_{10})^2 \right) \]

where

\[ A_1 \equiv \exp \left( -\frac{\delta^2}{4} + \frac{\delta^2}{4} + \gamma_1 + \frac{\gamma_1}{2} \right), \quad \gamma_1 = \delta + \gamma, \quad \text{and} \quad t_{10} = -\delta/\gamma. \]

Next, the pulse passes through the frequency-doubling crystal. The output pulse resulting from the passage is found by one application of the transfer function of the crystal [8]:

\[ V_3(t) = A_1 \exp \left( -\frac{\delta^2}{4} \gamma_1 + \frac{\delta^2}{4} - \frac{\delta^2}{4} - 2\delta \alpha_0 + \frac{\gamma_1}{2} \right) \]

where

\[ A_2 \equiv \exp \left[ -\gamma_2 (t + t_{10})^2 \right] \]

and \( \gamma_2 = \frac{1}{2} \delta + \gamma. \)

The \( \alpha_0 \) and \( \alpha_0^2/2 \) are the conversion efficiency to the SH wavelength and the linear insertion losses of the crystal for the single pass through its crystal, respectively. The process of the pulse broadening due to the SHG may be understood as follows. During the SHG process the power of the fundamental wave is passed through its crystal, respectively. The process of the pulse broadening due to the SHG may be understood as follows. The broadening due to the SHG may be understood as follows.

This is in contrast to the effect of the nonlinear absorption effect by a single parameter \( \alpha_0 \), defined as the average power conversion efficiency to the SH wavelength.

When the pulse passes the bandwidth-limiting element having the transfer function \( T(\omega) = \exp \left[ -D'(\omega - \omega_0)^2 \right] \), the envelope function becomes

\[ V_4(t) = \frac{A_2}{\sqrt{4D'\gamma_1 + 1}} \exp \left( -\frac{\gamma_2}{4D'\gamma_1 + 1} (t + t_{10})^2 \right) \]

where \( D' \equiv (2\sqrt{\ln 2}/\Delta\Omega)^2 \), and \( \Delta\Omega \) is the full bandwidth at half maximum point of the element. Furthermore, the pulse suffers a net roundtrip loss \( \alpha_0 \) including the output coupling effect, except for the losses relevant to the intracavity crystal, i.e., \( V_5(t) = \exp( -\alpha_0 ) V_4(t) \).

After the pulse is reflected by the output mirror, it again passes through the bandwidth-limiting element. The output \( V_6(t) \) is found by one more application of (9). This means that \( D' \) in (9) must be replaced by \( D \equiv 2D' \).

Similarly, \( V_6(t) \) is the input for the second pass through the frequency-doubling crystal, so that the output-field envelope \( V_6(t) \) becomes

\[ V_6(t) = A_1 \exp \left[ -\left( \frac{\sqrt{\delta^2 \alpha_0^2 + \alpha_1 + \alpha_0}}{4D(1 - \sqrt{2} \alpha_0) \gamma_1 + 1} \right) \right] \times \exp \left[ -\frac{(1 - 2\sqrt{2} \alpha_0) \gamma_1}{4D(1 - \sqrt{2} \alpha_0) \gamma_1 + 1} (t + t_{10})^2 \right]. \]

For self-consistency, the net modification of the pulse upon return to the starting point must be set equal to zero. That is, the initial input pulse \( V_6(t) \) must be the same as the final output pulse \( V_6(t) \), aside from a phase factor. This leads to three coupled equations by equating powers of \( t \)

\[ g + \frac{\delta^2}{4} - \frac{1}{2} \ln \left( \frac{32 \ln 2}{\Delta\Omega^2} (1 - \sqrt{2} \alpha_0) (\delta + \gamma) + 1 \right) - \sqrt{2} \]

\[ \cdot \alpha_0 - \alpha_1 = 0 \]

\[ \gamma = \frac{(1 - 2\sqrt{2} \alpha_0) (\delta + \gamma)}{32 \ln 2 \Delta\Omega^2} (1 - \sqrt{2} \alpha_0) (\delta + \gamma) + 1 \]

where the cavities length detuning \( \Delta L \equiv L_d - L_p \) is equal to \( -c \Delta t/2 \).

Equations (11), (12), and (13), respectively, represent the conservations of the pulse amplitude, the pulse duration, and the position of the pulse peak through a roundtrip. The fundamental equations provide a complete description of cavity length detuning characteristics of the SMLFD dye laser. That is, these can determine the duration \( \tau_p = [2 \ln 2/\gamma]^{1/2} \) of the pulse and the square \( |E_p|^2 \) of its peak intensity as a function of length detuning \( \Delta L \) for any SHG conversion efficiency \( \alpha_0 \) and limited bandwidth \( \Delta\Omega \) due to the intracavity crystal, as shown in the following section.

III. Solution to the Equations

From (4) and the saturation time \( T_s = [\alpha_0 E_p^2/2\hbar \omega_0]^{-1} \), the pulse energy \( \epsilon = E_p^2 [2 \ln 2/\gamma]^{1/2} \) is written

\[ \frac{\epsilon}{\epsilon_s} = \frac{\ln \left( \frac{\alpha_0}{\alpha_1} \right)}{\ln \left( \frac{\alpha_0}{\alpha_1} \right)} \times \text{erfc} \left( \frac{\Delta t}{\tau_p} \right) \]

where \( \epsilon_s \) is the saturation value [4]. The substitution of (12) and (13) into \( \delta \) and \( \tau \) in (11) enables us to describe \( g \) in (14) in terms of system parameters

\[ g = \alpha + \left( \frac{A_0}{2} - \left( \frac{A_0}{2} \right)^2 \right) \gamma_0 \]

where the effective total cavity losses \( \alpha \equiv \sqrt{2} \alpha_0 + \alpha_1 + \alpha_0 \), the effective bandwidth-limiting factor

\[ A_0 \equiv 32 \ln 2 \times (1 - \sqrt{2} \alpha_0)/\Delta\Omega^2 \]

and the pulse broadening factor due to SHG process \( B_0 \equiv 1 - 2\sqrt{2} \alpha_0 \).

\[ \gamma_0 \]

\[ \gamma_0 = \frac{\left( \left( \left( \Delta t + \tau_0^2 \right)^2 - B_0 \tau_0^2 \right)^2 + 4 \alpha A_0 B_0 \tau_0^2 \right)^{1/2}}{2 A_0 \tau_0^2} \]

where

\[ \tau_0 = (\sqrt{\pi} \tau_p/2) \times \text{erfc} \left( \Delta t/\tau_p \right) \times \exp \left( \Delta t/\tau_p \right)^2. \]

Here, the third term in (11) has been expanded to first order, and the term \( (\alpha - \frac{1}{2}) A_0 \) in \( \gamma_0 \) has been neglected. Equation
with the use of (15) and (16) enables us to determine the pulse energy of the fundamental wave in the SMLFD dye laser. When the second term in (15) is neglected without the intracavity SHG effect, (14) corresponds to (9) in [4] for the usual SML laser.

Next, we describe the pulse duration of the fundamental wave in terms of the system parameters in the SMLFD dye laser. The substitution of (5) and (14) into one of the fundamental equations yields the cubic equation for $\gamma^{1/2}$

$$A_0 \gamma^{3/2} + A_0 F \gamma + (1 - B_0) \gamma^{1/2} - B_0 F = 0$$

where

$$F = (4 \sqrt{2} g_0 / \pi \Delta \gamma^2) \times \exp \left[ - (\Delta t / \Delta \gamma^2) \right] \times \exp \left[ - (e / e_0) \right] / e / e_0.$$

Solving by the Cardan approach [9], we obtain the positive solution

$$\gamma^{1/2} = \alpha^{1/3} + \beta^{1/3} - \frac{F}{3}$$

and

$$a = (9(1 + 2B_0)F^2 - 2A_0 F^3 \pm 3 \sqrt[3]{[A_0^2 (41 - B_0)^3 - A_0 F^3 (1 - 2B_0 - 8B_0^2 + 4A_0^2 F 3/2] / 54 A_0})$$

Therefore, the pulse duration $\tau_p = [2 \ln 2 / \gamma]^{1/2}$ is determined by the use of (18) and (19). If $6 \sqrt{2} e_0 A_0 F^2 \gg A_0^3$, simplification of (18) and (19) can be made

$$\gamma^{1/2} = \alpha^{1/3} + \beta^{1/3};$$

hence, the corresponding pulse duration is

$$\tau_p = (2 \ln 2)^{1/2} \times \{3A_0 / (2B_0 + 1) F \}^{1/3}.$$

This reduces to (11) in [4] when $\alpha_0 = \gamma_0 = 0$.

IV. EFFECTS OF INTRACAVITY SHG CRYSTAL ON PULSE DURATION

The experiment on a SMLFD rhodamine 6G laser pumped by an Ar ion laser has been carried out by employing an ADP crystal of a different length as a frequency-doubler [1], [2]. For confirmation of the analysis, we compare the experimental results by the use of laser parameters of the system. The relevant parameters are summarized in Table I [1].

Fig. 2 shows the variations of the duration $\tau_p$ and the square $(e / e_0)^2 / \tau_p^2$ of the peak intensity of the fundamental pulse as a function of length detuning $\Delta L$ for different crystal-length $l$. The behavior of the variations explains well the experimental fact that the cavity length where the pulse duration becomes minimum is shorter by several mm than the length where the SH intensity of the autocorrelation signal becomes maximum [1], [2]. From Fig. 2 we also find that with increase of the crystal length the pulse duration is broadened, which agrees with the experimental findings. The increase of the crystal length brings about not only the quadratic increase of the nonlinear losses $\alpha_0$ due to the SHG process, but also the linear decrease of the intracavity bandwidth $\Delta \Omega$ due to the birefringence effect of the crystal. The bandwidth $\Delta \Omega_{1.5}$ employed in the calculation is adjusted so that both the theoretical and experimental minima of the pulse duration in the case of the 1.5 mm length $l_{1.5}$ of the ADP crystal coincide. For different crystal lengths, the bandwidth $\Delta \Omega_{1.5}$ employed is equal to the product $l_{1.5} \cdot \Delta \Omega_{1.5} / l$ between the bandwidth $\Delta \Omega_{1.5}$ for the 1.5 mm length and the inverse ratio of each crystal length $l$ to the 1.5 mm length $l_{1.5}$, since the bandwidth is inversely proportional to its length [10]. The calculated values of the minimum pulse duration for different crystal lengths are given in Table I with the ones obtained experimentally [1].

Next, we consider separately, the effect of the nonlinear losses $\alpha_0$ corresponding to the practical conversion efficiency of SHG and the bandwidth-limiting effect $\Omega_{1.5}$ of the crystal on the pulse duration. The calculated dependence of the minimum pulse duration on the conversion efficiency with keeping the intracavity bandwidth constant is shown in Fig. 3. On the other hand, in Fig. 4 the dependence of the pulse duration on the bandwidth while keeping the conversion efficiency constant is shown. From these figures it is established that the pulse duration increases rapidly as the increase of the conversion efficiency is more than $\alpha_0$, $2 \times 10^{-3}$ and as the decrease of the bandwidth is less than $\Delta \Omega_{1.5}$. Therefore, it is deduced that in the present experimental system both the effects of the nonlinear losses due to the SHG process and the intracavity bandwidth-limiting due to the birefringence of the crystal, cause the pulse broadening by nearly the same degree.

All the numerical values, thus far, have been calculated by
Fig. 2. Variation of the pulse duration (solid lines) and the square of its peak intensity (dashed lines) of the fundamental wave as a function of cavity length detuning for different lengths of the intracavity SHG crystal. The reference point of \( \Delta L = 0 \) is taken at the point of the cavity length where the square of the pulse peak intensity is maximum.

Fig. 4. Dependence of the minimum pulse duration on the intracavity bandwidth for different conversion efficiencies to the SH wavelength.

V. CONCLUSION

This paper has analyzed the characteristics of a SMLFD dye laser. For different lengths of the intracavity crystal, the variation of the pulse duration and the square of its peak intensity as a function of cavity length detuning has been derived. Furthermore, the dependence of the pulse duration on the conversion efficiency of SHG has been given. It has been shown that these analytical predictions explain quite well the results obtained from the experiment on a SMLFD rhodamine 6G laser with ADP crystal in the cavity.
