Recently synchronously or synchronous-passive hybrid mode-locked (HML) cw dye lasers were used as reliable sources of picosecond and subpicosecond pulses tunable in the visible and near-IR regions. In addition, continuous trains of UV picosecond pulses have been produced by intracavity second harmonic generation (SHG) in a synchronous mode-locked (SML) cw dye laser and employed for studying fast photochemical reactions of molecules. In all the cases it was reported that the pulse duration and shape are critically dependent on the dye laser cavity length. That is, generation of stable tunable ultrashort pulses is closely related to the time of arrival of the dye pulse at the dye jet after the round trip in the cavity with respect to the time evolution of the gain induced by the pump pulse. The subject of this Letter is to disclose experimentally the relationship between gain behavior varying on a picosecond time scale and pulse formation for cavity length detuning using continuous pump-probe gain spectroscopy.

The experimental arrangement for simultaneous measurements of the gain evolution and autocorrelation trace of the pulse vs cavity length detuning is shown in Fig. 1. A mode-locked Ar-ion laser (Spectra-Physics 171-18UV) with the average power of 1.6 W at 514.5 nm (~150-psec pulse duration) is used as the excitation source of a separation-type synchronous-passive HML cw dye laser providing probe pulses. The gain sample to be measured is the lasing dye itself (1 × 10⁻³-M rhodamine 6G in ethylene glycol) of the HML dye laser. The cavity of the HML laser consists of the two concave mirrors for focusing the excitation pulse on the laser dye and collimating the dye laser beam, two other concave mirrors for focusing the laser beam on the saturable dye (8 × 10⁻⁶-M DODCI in ethylene glycol), and an output mirror (~10% transmission at 600 nm). The wavelength of the laser...
Therefore, the arrival time of the dye pulse, which is shown in Fig. 2, can be distinctly defined from the autocorrelation trace of the left side in Fig. 2, when the cavity length adjustment $M$ is taken at the point of the cavity length where the gain level, while the substructure in the pulse is suppressed. For cavities slightly shorter ($M = -1.5 \mu m$) than for maximum SHG, the height of the cone is relatively lowered as high as the following recovered-gain level, while the substructure in the pulse is suppressed and the shortest pulse of 0.79-psec duration is produced. Further shortening of the cavity (from $\Delta L = -5$ to $-10 \mu m$) continues to lower the cone height of the gain and broaden the pulse duration gradually to 2.1 psec. For the shortest cavities of $\Delta L = -16.5 \mu m$, the cone of the gain remains obscure in the gain rising process, while the autocorrelation trace does not show the contrast ratio of 3:1 and satellite pulses occur. As for a series of autocorrelation traces this behavior agrees well with already reported results,1-5 even though the cavity length is too long a sharp cone occurs in the vicinity of the gain peak while, as for the autocorrelation trace, a broad pedestal betraying the presence of substructure in the pulse occurs. The gain evolution is similar to the result obtained from the fluorescence signal from the dye jet by an optical light-gate technique except that the gain cone is much sharper. The difference is presumably due to the present technique being better in time resolution than the light-gate technique. As the cavity length is shortened the cone is sharpened, while the pedestal becomes less broad indicating a $\sim$5.5-psec pulse duration of still with a structure. For cavities slightly shorter ($\Delta L = -1.5 \mu m$) than for maximum SHG, the height of the cone is relatively lowered as high as the following recovered-gain level, while the substructure in the pulse is suppressed and the shortest pulse of 0.79-psec duration is produced. Further shortening of the cavity (from $\Delta L = -5$ to $-10 \mu m$) continues to lower the cone height of the gain and broaden the pulse duration gradually to 2.1 psec. For the shortest cavities of $\Delta L = -16.5 \mu m$, the cone of the gain remains obscure in the gain rising process, while the autocorrelation trace does not show the contrast ratio of 3:1 and satellite pulses occur. As for a series of autocorrelation traces this behavior agrees well with already reported results.1-5 From the movement of the dip position in the gain evolution it is also found that, as the cavity length is shortened, the dye pulse arrives slightly early at the dye jet. It seems that...
Fig. 3. Measured gain evolutions during SML action (solid line) and no laser action (dotted line) under the low pumping power. A narrow horizontal line $L$ represents the threshold level in SML action.

Fig. 4. Wavelength dependence of the gain peak for a rhodamine 6G jet stream in the case where laser action was stopped.

The measured gain evolution during SML action and that without laser action under the same low pumping power ($\sim 1.2$ times the threshold power) are shown by solid and dotted lines in Fig. 3, respectively. The narrow horizontal line $L$ represents the loss level of the SML laser which was estimated from the comparison between the pumping power at the operational condition and that at the threshold. From the dotted line it is found that when laser action is stopped the gain first rises with a rising time of $\sim 130$ psec and then drops slowly with $\sim 2.5$-nsec dye lifetime. This rising behavior corresponds to the fact that the gain around the arrival of the pump pulse under no laser action is proportional to the integral of the intensity of the pump pulse, which was suggested in Ref. 9. The total evolution is similar to that obtained in a rhodamine B solution except for the quantitative values. From the comparison between dotted and solid lines it is also found that the gain during mode-locking action is depleted in the vicinity of the peak due to stimulated emission by the intracavity dye pulse. However, in the present experimental conditions it is difficult to define distinctly the arrival time of the dye pulse in the gain evolution because of the relatively low pumping power.

Furthermore, the wavelength dependence of the gain peak in the case of no laser action was examined (see Fig. 4). For wavelengths shorter than $567$ nm, however, the gain measurement could not be made since the power of the probe pulse in its wavelength region was too low. Figure 4 shows that the gain increases rapidly in the wavelength region shorter than $560$ nm in contrast to the wavelength dependence of the usual dye laser output whose blue shift was also observed for a rhodamine B solution. This difference is presumably due to the following fact: in the case of a measured single-pass gain the reabsorption loss of the dye itself at the long-wavelength edge of the absorption spectra where the spectra overlap with the fluorescence spectra is much less effective than that due to the multiple-pass effect in the cavity in the case of laser action.

To summarize: it has been demonstrated that a continuous pump- and gain-probe technique is useful for an experimental study on a picosecond time scale of synchronous-passive hybrid mode-locking mechanisms in a cw dye laser. Cavity length detuning characteristics of the time evolution of the gain have been discussed in connection with the pulse autocorrelation trace. In addition, the difference between gain evolutions during mode locking and no laser action has been experimentally confirmed. The wavelength dependence of the small-signal gain has also been examined.

We gratefully acknowledge N. Haga and T. Katakura for their help with the experimental work.
