Abstract

Prolyl oligopeptidase (POP) is a serine endopeptidase which selectively digests a -Pro-X- peptide bond. Our previous study showed that POP mRNA was strongly expressed in the spongiotrophoblast of the mouse placenta at E17.5, suggesting its importance in development. To gain more insight into POP's role during gestation, we investigated its expression using different developmental stages of placenta. As a result of *in situ* hybridization, we found that localization of POP mRNA changed at E12.5. POP mRNA was strongly expressed in the spongiotrophoblast and labyrinth at E10.5 and E11.5 but thereafter only in the spongiotrophoblast. Immunohistochemistry revealed that POP was present in the parietal trophoblast giant cell, the spongiotrophoblast cell, and the labyrinth at E11.5 but the strong expression in the labyrinth was maintained only in the canal-associated and sinusoidal trophoblast giant cells at E16.5 and E18.5. To determine subcellular distribution of the POP protein, we fractionated the placental extract into cytoplasmic, membrane, and nuclear subfractions. By Western blot analysis, POP was detected in the cytoplasmic and membrane fractions but not in the nuclear fraction at E11.5 and E16.5. Interestingly, the cytoplasmic POP exhibited higher enzymatic activity than the membrane-associated type. These data suggest that the cytoplasmic and membrane-associated POP have distinct roles in different types of placental cells.

Key words: prolyl oligopeptidase, localization, placenta, spongiotrophoblast, trophoblast giant cell, subcellular distribution

1 Abbreviations: ANOVA, analysis of variance; C-TGC, canal-associated TGC; E, embryonic day; MCA,

1 **Introduction**

2
3 Prolyl oligopeptidase (POP, E.C.3.4.21.26, prolyl endopeptidase, post proline cleaving enzyme; gene
4 symbol *Prep*) is a serine endopeptidase which hydrolyzes a peptide bond at carboxyl side of an internal
5 proline residue (Wilk, 1983). POP has an ancient origin and is distributed in various species from bacteria
6 to mammals (Garcia-Horsman et al., 2007), and in higher organisms most tissues express it at different
7 levels (Myöhänen et al., 2009). Because of its peculiar activity and wide distribution, the physiological
8 role of POP has received intense interest since its discovery in 1971 (Walter et al.). The most studied
9 tissue is the brain because POP has been reported to be related to learning and memory and may be a
10 cause of some neurodegenerative diseases such as bipolar disorder and Alzheimer disease
11 (Garcia-Horsman et al., 2007; Myöhänen et al., 2009; Williams, 2004). With regard to this, POP-deficient
12 mice exhibited a defect in growth cone dynamics of neurons (Di Daniel et al., 2009). In pituitary, POP has
13 been shown to process α -melanocyte stimulating hormone (α MSH) and affect obesity (Perroud et al.,
14 2009; Warden et al., 2009). POP has also been suggested to be involved in cell proliferation and
15 differentiation in murine Swiss 3T3 cells (Ishino et al., 1998) and *Sarcophaga peregrina* (flesh fly)
16 (Ohtsuki et al., 1994, 1997), but its physiological function still needs to be explored.

17 Another important issue about POP is the subcellular localization. POP had been thought to be a
18 cytosolic protein, but a membrane-bound form was recently purified from porcine brain and characterized
19 (Tenorio-Laranga et al., 2008). Other results have suggested the existence of a secreted form (Kimura et
20 al., 1998, 2002; Soeda et al., 1984; Takahashi et al., 1996), and in mammalian cultured cells and some
21 mouse peripheral tissues, POP was also localized to the nucleus (Ishino et al., 1998; Myöhänen et al.,
22 2008c). Therefore, POP is now thought to be present in various forms although it is encoded by a single
23 gene (Kimura et al., 1999; Kimura and Takahashi, 2000). This is consistent with a recent report indicating
24 that POP was associated with the cytoplasm, nucleus, and membrane in the cerebellar granule cell culture
25 (Moreno-Baylach et al., 2008). However, it is still unclear whether the nuclear and membrane-associated

POP is commonly present in many tissues of many species.

The nuclear POP is often linked to development and differentiation. The POP enzymatic activity or its mRNA expression have been reported to be high at early developmental stages of the rat brain (Kato et al., 1980; Fuse et al., 1990; Yamanaka et al., 1999; Agirregoitia et al., 2003, 2010), pituitary (Agirregoitia et al., 2003), and liver (Matsubara et al., 1998) as well as of the mouse testis (Kimura et al., 2002).

Because these stages are when cells proliferate and differentiate in each tissue, POP is presumed to be involved in cell cycle regulation and the nuclear POP is believed to be responsible for this role. In fact, a very recent report showed that POP was localized to the nucleus only early in the brain development (Hannula et al., 2010). Although there is no conclusive evidence for the nuclear POP controlling the cell cycle, it is widely accepted that POP plays some important roles in development and differentiation.

Consistent with this, we observed a relatively high level of POP mRNA expression in the mouse embryo during early gestation (Matsubara et al., 2010).

The placenta plays a critical role in fetal development by forming an interface between the maternal and fetal circulation. The developed mouse placenta is mainly composed of three layers: the outer maternal decidua, middle junctional zone, and innermost labyrinth layer. The maternal decidua contains decidual cells, which originate from the uterus, and maternal vasculature to transport blood to the fetus. The labyrinth layer includes highly branched maternal and fetal vasculatures composed of several distinct cell types for efficient exchange of nutrients and gases. Separating these two, the junctional zone consisting of the spongiotrophoblast and glycogen trophoblast cell supports the labyrinth structurally and functionally by producing many angiogenic and tissue remodeling factors (Rossant and Cross, 2001). In addition, the mouse placenta includes four subtypes of trophoblast giant cells (TGCs) that play important roles in the maintenance of pregnancy by secreting many hormones and paracrine factors (Hu and Cross, 2010; Simmons et al., 2007). Parietal TGC (P-TGC) positions between the maternal decidua and junctional zone, and spiral artery-associated TGC (SpA-TGC) lines maternal spiral arteries in the decidua. Canal-associated TGC (C-TGC) and sinusoidal TGC (S-TGC) are found in the labyrinth. Many genes are

thought to be involved in the regulation of placental functions (Watson and Cross, 2005) but the molecular mechanisms are still poorly understood.

In the mouse, POP mRNA is highly expressed in the ovary and placenta (Matsubara et al., 2010), suggesting its importance in reproduction and development. As an initial step toward understanding the physiological function of POP in development, here we investigated its expression and localization in different developmental stages of placenta. We found that the localization of POP mRNA and protein changed at embryonic day (E)12.5. POP was strongly expressed in P-TGCs, spongiotrophoblast cells, and the labyrinth layer before E12.5, but only C-TGCs and S-TGCs maintained the strong expression in the labyrinth after that. We also assessed the subcellular distribution of POP in the placenta and found that POP was localized in the cytoplasm and membrane but not in the nucleus. These results suggest that the distinct forms of POP contribute to different placental functions.

Materials and methods

Animals and tissue preparation

C57/BL6 and BDF1 (C57/BL6 × DBA2 F1) mice were obtained from CLEA Japan Inc. (Tokyo, Japan) and maintained under standard conditions, with free access to food and water, and a 14-h light/10-h dark cycle. Tissues were collected as previously described (Matsubara et al., 2010). All the placentas were isolated with the maternal decidua. The experimental procedures used in this study were approved by the Institutional Animal Use and Care Committee at Hokkaido University.

Detection of RNA

Northern blot and *in situ* hybridization analyses were performed as previously described (Matsubara et al., 2010).

POP activity assay

We homogenized each placenta (E10.5-E18.5) in ice-cold phosphate-buffered saline (PBS). The homogenate was centrifuged at 15,000 rpm for 5 min at 4°C and the supernatant was used for the enzymatic activity assay. The subcellular fractions were prepared as below. The specific POP activity toward Suc-Gly-Pro-Leu-Gly-Pro-4-methylcoumaryl-7-amide (MCA; Peptide Institute, Osaka, Japan) was measured as previously described (Kimura et al., 1998).

Expression and purification of recombinant mouse POP

An open reading frame of mouse POP was subcloned into pET30a expression vector (Novagen, Madison, WI) (Kimura et al., 2002). Expression of the recombinant mouse POP in the *Escherichia coli* expression system was carried out according to the method of Ogiwara et al. (2005). The recombinant POP was produced as a fusion protein with a vector-derived N-terminal sequence containing His-tag and an S-protein. Harvested cells were suspended in 0.1 M Tris-HCl (pH 8.0), lysed by freeze-thaw method, sonicated, and centrifuged at 9,000 rpm for 15 min at 4°C. The supernatant was filtered with Minisart filter unit (0.45 µm pore size, Sartorius Biolab Products, Goettingen, Germany) and subjected to Ni²⁺ affinity chromatography (GE Healthcare Biosciences, Piscataway, NJ). The recombinant POP was eluted with the buffer containing 50 mM histidine. In order to remove an extra amino acid sequences, approximately 650 µg of the POP protein was incubated with 3 µl of medaka enteropeptidase in Enteropeptidase Buffer (20 mM Tris-HCl, 50 mM NaCl, 2 mM CaCl₂, pH 7.4) for 16 h at 26°C (Ogiwara and Takahashi, 2007). Then the recombinant POP was separated on a Resource Q column with AKTA

Purifier (GE Healthcare Biosciences) in 50 mM Tris-HCl (pH 8.0) and fractions with high POP activity were collected. After the removal of the extra peptide using the Ni²⁺ sepharose column, the recombinant POP was further purified by Mono Q column with AKTA Purifier (GE Healthcare Biosciences) in 50 mM Tris-HCl (pH 8.0). We confirmed a single band of the recombinant POP by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Coomassie Brilliant Blue staining. To exchange the buffer at each step, we used VIVASPIN 20 centrifugal concentrator (10,000 MWCO, PES, Sartorius Biolab Products).

Generation and purification of polyclonal anti-POP antibody

We obtained approximately 3.5 mg purified recombinant POP protein from about 20 liters of the bacterial culture. Two hundred micrograms of the protein were injected into a chicken every two weeks and the antiserum was checked by Western blot analysis at 5 and 10 weeks after the first injection. Specific anti-POP antibody was purified from the serum by the method using Western blot. We injected the antigen into three chickens (C1, C2, C3) and the antiserum from the C1 chicken was used in this study. Excess amount of the recombinant POP was separated by SDS-PAGE and blotted to the polyvinylidene difluoride membrane (PVDF, Millipore, Bedford, MA). After the position of the POP signal was confirmed by staining the 1 cm side of the membrane, the band including POP was cut out from the remaining membrane. Blocking was conducted as below and the membrane was incubated for overnight at 4°C with 500 µl antiserum combined with the same volume of PBS containing 0.1% Tween 20 (PBST). The membrane was washed with PBST for 10 min three times and incubated with 10 ml of Elution Buffer (0.1 M Glycine-HCl, 0.5 M NaCl, pH 2.4) for 20 min with shaking. The eluted antibody was neutralized by adding 2 ml of 2 M Tris-HCl (pH 8.0). The buffer was exchanged to PBS and the antibody was concentrated to 200 µl by using VIVASPIN 20 (Sartorius Biolab Products). The antibody was mixed with the same volume of glycerol and stored at -20°C until use. The antibody concentration was determined

with BCA Protein Assay Reagent Kit (Pierce, Rockford, IL).

Western blot analysis

Twenty micrograms of each sample was electrophoresed on an 8% SDS-PAGE gel and blotted to a PVDF membrane (Millipore). After blocking with Block Ace (Dainippon Seiyaku) and normal rabbit serum (1:250 dilution with PBST) for 1 h each at room temperature, the membrane was incubated with the antibody for 1 h at room temperature. The antibodies used in this study were the purified anti-POP antibody (10 µg/ml at a final concentration), anti-β-actin monoclonal antibody (1:1000 dilution, Sigma, St Louis, MO), anti-histone H3 antibody (1:100 dilution) (Kimura et al., 2008), and anti-connexin 43 antibody (1:500 dilution, Transduction Laboratories, Lexington, KY). The antibodies for POP were diluted with ExactaCruz™ E Dilution Buffer (Santa Cruz Biotechnology, Santa Cruz, CA), and for β-actin, histone H3, and connexin-43 with PBST. The membrane was further incubated for 1 h at room temperature with the secondary antibody, goat anti-chicken IgY antibody (1:10000 dilution, Jackson ImmunoResearch, West Grove, PA) for POP and anti-mouse IgG antibody (1:5000 dilution, GE healthcare) for the other antibodies. The signals were detected using an Immobilon Western Chemiluminescent HRP Substrate (Millipore) according to the manufacture's instruction. To confirm the specificity of the generated antibody, we conducted the same experiment by using the POP antibody preincubated with the purified recombinant POP.

Immunohistochemistry

Placentas were fixed at 4°C for overnight in Bouin's solution, embedded in paraffin, and sectioned at 6 µm. The sections were dewaxed in xylene for 10 min and rehydrated in serial ethanol solution and running tap water. The slides were boiled using a microwave oven in 10 mM citric acid buffer (pH 6.0)

for 5-10 min and cooled for 15 min at room temperature. Endogenous peroxidase activity was quenched by incubating the slides with 2.25% hydrogen peroxide for 15 min. After being washed with running tap water and PBS for 5 min each, the slides were blocked as in Western blot. The sections were incubated with the purified anti-POP antibody (40 µg/ml at a final concentration) for 12 h at room temperature and washed with PBS for 5 min three times. After being incubated with the secondary anti-chicken IgY antibody (1:500 dilution) for 3 h at room temperature and washed with PBS, the signals were developed using AEC Peroxidase Substrate kit (Vector Laboratories, Inc., Burlingame, CA) for 20-30 min. For negative controls, slides were incubated without the primary antibody or with the POP antibody preincubated with the purified recombinant POP at that step. After the signal was developed, the sections were counterstained with Carazzi's hematoxylin for 5min.

Preparation of subcellular fractions

To obtain subcellular fractions from the placenta, we applied two different methods. The first one was to separate the cytoplasmic and membrane subfractions from the nuclear subfraction. We homogenized the placenta at E10.5 and E15.5 in 1 ml of ice-cold Sucrose Buffer I (0.32 M sucrose, 3 mM CaCl₂, 2 mM magnesium acetate, 0.1 mM EDTA, 10 mM Tris-HCl, 1 mM dithiothreitol (DTT), 0.5 mM phenylmethylsulfonyl fluoride, 0.5% NP-40, pH 8.0) and the homogenates were centrifuged at 3,000 rpm for 5 min at 4°C. The supernatant contained cytoplasmic and membrane-associated proteins and the precipitate was the nucleus. We collected the supernatant by adding 220 µl of 5× Extraction Buffer (0.15 M HEPES-KOH, 0.7 M KCl, 15 mM MgCl₂, pH 7.9) and centrifuging it at 12,000 rpm for 15 min at 4°C (designated as 'C+M'). The nucleus was suspended in 1 ml of Sucrose Buffer I lacking NP-40 and centrifuged at 3,000 rpm for 5 min at 4°C. The precipitates were resuspended in 200 µl of Low-Salt Buffer (20 mM HEPES-KOH, 25% Glycerol, 1.5 mM MgCl₂, 20 mM KCl, 0.2 mM EDTA, 0.5 mM DTT, pH 7.9), and the same volume of High-Salt Buffer (20 mM HEPES-KOH, 25% Glycerol, 1.5 mM MgCl₂,

0.8 M KCl, 0.2 mM EDTA, 0.5 mM DTT, pH 7.9) was mixed with the nucleus by adding 50 µl four times. The total volume of 400 µl including the nuclear protein were incubated for 20 min at 4°C with gentle rotation and then 800 µl of Diluent (25 mM HEPES, 0.1 mM EDTA, 0.5 mM DTT, pH 7.6) were added. After centrifugation at 15,000 rpm for 15 min at 4°C, the supernatants were collected (designated as 'N').

The second procedure was to prepare the cytoplasmic, membrane, and nuclear subfractions separately. The experiment was performed as described by others with slight modifications (Ogiwara and Takahashi, 2007). We homogenized the placenta at E11.5 and E16.5 in 1 ml of ice cold buffer A (10 mM Tris-HCl, 10 mM MgCl₂, 10 mM KCl, 1 µM DTT, pH 7.5) containing 1× proteinase inhibitor cocktail (Roche Molecular Biochemicals, Mannheim, Germany) and centrifuged the homogenate at 1,600 × g for 8 min at 4°C. The precipitate was treated as in the first method and the obtained extract was designated as the nuclear subfraction (N). The supernatant was further centrifuged at 100,000 × g at 4°C for 30 min and the resulting supernatant was the cytoplasmic subfraction (C). The precipitate was washed with 1.5 ml of 0.1 M Tris-HCl (pH 8.0), centrifuged again at 100,000 × g at 4°C for 30 min, and suspended in 0.1 M Tris-HCl (pH 8.0) (M). All samples were sonicated using a Tomy Ultrasonic Disrupter UD-201 (Tomy, Tokyo, Japan) with 20% output for 5 s 3 times.

Statistical analysis

Results were expressed as the average ± standard deviation (SD) of at least three independent experiments and analyzed by Student's *t* test or one-way analysis of variance (ANOVA) followed by Tukey's *post hoc* test using JSTAT statistical software (version 12.6 for Windows, Masato Sato, Japan). Differences were considered statistically significant at *P*<0.05.

Results

Tissue distribution of POP mRNA and its localization in the placenta.

We previously showed that the ovary and placenta expressed a higher level of POP mRNA than the liver, testis, and uterus (Matsubara et al., 2010). We extended this analysis to 16 mouse tissues and performed a Northern blot analysis. Although the lung RNA seemed to be degraded, the result indicated that the ovary and placenta expressed the highest level of POP mRNA in the tissues (Fig. 1). We then investigated the localization of POP mRNA in the placenta at E10.5-E18.5. Consistent with our previous result of the E17.5 placenta (Matsubara et al., 2010), POP mRNA was strongly expressed in the spongiotrophoblast at E12.5-E18.5 (Fig. 2A). However, in the E10.5 and E11.5 placenta, a strong signal was detected in both the spongiotrophoblast and the labyrinth layer (Fig. 2A). Higher magnification images of the E11.5 and E15.5 placenta, which represent the two types of staining patterns, suggested that S-TGC was the only cell type that maintained the POP mRNA expression in the labyrinth at E15.5 (Fig. 2B). We could also identify P-TGC in the junctional zone which was stained at both E11.5 and E15.5 and the decidual cell was weakly stained in both the placentas (Fig. 2B). Flt1 was used as a marker of the spongiotrophoblast in the neighboring section (Hitz et al., 2005). No positive signal was obtained in the sections hybridized with POP and Flt1 sense probes (Fig. 2A). Sections stained with hematoxylin and eosin were provided to show the morphology of each region of the placenta (Fig. 2B). The data indicated that the mouse placenta expressed a high level of POP mRNA and its localization changed at E12.5.

Placental POP activity and protein amount during gestation.

We next examined the expression of POP protein in the placenta by measuring the enzymatic activity and performing Western blot analysis (Fig. 3). We prepared soluble extracts from E10.5-E18.5 placentas and measured the POP activity toward an MCA substrate Suc-Gly-Pro-Leu-Gly-Pro-MCA since

POP is the only known enzyme that can digest this substrate. The result showed that the activity gradually increased about 2-fold between E10.5 and E14.5 and the high level of activity was kept until E18.5 (Fig. 3A). For Western blot analysis, we generated and purified the POP antibody as described in materials and methods. We first used the extracts of the brain and E18.5 placenta for the analysis and detected a single band at 72 kDa (Fig. 3B, left). To confirm the specificity of the 72-kDa band, we conducted the same experiment by using the POP antibody preincubated with the recombinant POP and this resulted in disappearance of the band (Fig. 3B, right). The data indicates that the POP antibody we generated specifically recognizes the POP protein. We then assessed the POP protein expression in E10.5-E18.5 placentas by using β -actin as a loading control and found that it was present at a constant level during this period (Fig. 3C, D). This is in agreement with the profile of the POP mRNA level, which was also constant during the same period (Matsubara et al., 2010), but is not consistent with the POP activity (Fig. 3A).

Localization of POP protein in the placenta.

To identify the cell type expressing POP protein, we next conducted the immunohistochemistry using E11.5, E16.5, and E18.5 placentas. We chose the E11.5 and E16.5 placenta as representative stages of the two expression patterns of POP mRNA (Fig. 2) and the E18.5 placenta as a fully mature stage. The strong POP signal was detected in the junctional zone and the labyrinth layer in the E11.5 placenta but the signal in the labyrinth dramatically decreased at E16.5 and E18.5 (Figs. 4A, 5A, M). Higher magnification of figures showed that all P-TGCs and spongiotrophoblast cells strongly expressed POP protein at the three stages (Figs. 4C, D, 5C, D, O-R). Glycogen trophoblast cells, which appear after E12.5 (Simmons and Cross, 2005), were very weakly stained in the E16.5 or E18.5 placentas (Fig. 5I, J, Q, R). The labyrinth layer contains several types of cells such as syncytiotrophoblast cells, the fetal vascular endothelium, and the allantois as well as S-TGCs and C-TGCs. In the E11.5 placenta, most labyrinthine cells showed a

positive POP signal and the only exception was the allantois (Fig. 4E, F). By contrast, we observed a strong POP signal almost exclusively in S-TGCs and C-TGCs in the labyrinth at E16.5 and E18.5 (Fig. 5E-H, S-V). The allantois was negative for POP immunoreactivity at these two stages, too (Fig. 5K, L, S, T). In the E18.5 placenta, we could also identify SpA-TGCs, which were stained (Fig. 5W, X). The maternal decidua showed weak POP immunoreactivity at all the stages examined (Figs. 4A, 5A, M). No signal was observed in any placental cells on the control sections treated without the POP antibody (data not shown) or with the POP antibody preincubated with the purified recombinant POP (Figs. 4B, 5B, N). The results of our immunohistochemistry are summarized in Table 1. These data suggest that POP protein is strongly expressed in the S-TGC, P-TGC, the spongiotrophoblast cell, and most cells of the labyrinth layer before E12.5 and in the spongiotrophoblast and four subtypes of TGCs after that. Interestingly, the signal seemed to be localized in the cytoplasm of all the POP-positive cells at all the stages examined.

Subcellular distribution of placental POP.

The immunohistochemistry suggested that POP protein was localized in the cytoplasm of all the POP-expressing placental cells. However, we could not tell whether the POP protein is associated with membrane or not. Therefore, we fractionated the placental extract into cytoplasmic, membrane, and nuclear subfractions. We applied two different methods to the fractionation. In the first method, we separated the combined cytoplasmic and membrane extract (C+M) from the nuclear extract (N) to confirm that POP was not localized to the nucleus. We checked the POP activity of each fraction and found that the C+M fraction had high POP activity in both the E10.5 and E15.5 placentas, whereas no significant activity was detected in the N fraction (Fig. 6A). Western blot analysis demonstrated that POP protein exists only in the C+M fraction (Fig. 6B). The results indicated that the placental POP protein was not localized to the nucleus.

We next separated the cytoplasmic, membrane, and nuclear subfractions by using the second method.

As a result of the enzymatic activity assay, the cytoplasmic extract showed much higher POP activity than the other two fractions in both E11.5 and E16.5 placentas (Fig. 6C). Interestingly, the membrane subfraction still showed higher POP activity than the nuclear extract, although the difference was not statistically significant. By Western blot analysis, we observed a POP signal in both the cytoplasmic and membrane fractions but not in the nuclear fraction (Fig. 6D). Antibodies against histone H3 and connexin-43 were used as markers of the nucleus and plasma membrane respectively and the results confirmed that our fractionation was successful (Fig. 6D). To compare the POP activity in the cytoplasm and membrane, we repeated Western blot analysis three times and quantified each signal by using the Image J software to normalize the POP band intensity to β -actin. As a result, the amounts of cytoplasmic POP in E11.5 and E16.5 placentas were 2.3- and 3.3-fold higher, respectively, than in the membrane-associated POP (Fig. 6D). Because the activities of the cytoplasmic extracts in E11.5 and E16.5 placentas were 15.3- and 12.7-fold higher, respectively, than in the membrane fractions (Fig. 6C), the activity of the cytoplasmic POP was probably higher than that of the membrane-associated POP. These results indicated that placental POP was localized in the cytoplasm and membrane, and that the membrane type seemed to have lower enzymatic activity.

Discussion

Tissue distribution of POP.

We first assessed the POP mRNA expression in 16 mouse tissues and found that the ovary and placenta expressed relatively high levels of POP mRNA (Fig. 1). This appears to be inconsistent with several studies reporting that the brain contained higher POP activity than other tissues (Fuse et al., 1990; Hersh 1981; Irazusta et al., 2002). However, the studies did not include the ovary and placenta for the

assay and one report indicated that the ovary contained higher POP activity than the brain in the mouse (Ohta et al., 1992). In addition, many reports have suggested that POP enzymatic activity is not necessarily consistent with its mRNA level and protein amount (Bellemère et al., 2004; Garcia-Horsman et al., 2007; Irazusta et al., 2001; Myöhänen et al., 2007, 2008a,b), possibly due to post-transcriptional or post-translational modifications or the existence of endogenous POP inhibitors (Salers, 1994; Soeda et al., 1985). Thus, what we can say from the current study is that at least in the mouse, POP mRNA is expressed at higher levels in the ovary and placenta than the brain.

Our result also uncovered the species difference of the POP mRNA distribution. The human POP mRNA was reported to be expressed at the highest level in the skeletal muscle but at low levels in the ovary and placenta (Goossens et al., 1997; Shirasawa et al., 1994). In the rat, the brain expressed a relatively high level of POP mRNA although the study included neither the ovary nor the placenta (Kimura and Takahashi, 2000). Porcine POP mRNA was expressed at much higher levels in the heart and muscle than the ovary (Rennex et al., 1991). These indicate that the tissue expressing POP mRNA at a high level is different between species and suggest that POP may have different roles in various species.

Molecular mass of POP.

We generated the new POP antibody which detected a 72-kDa band as the mouse POP protein (Fig. 3B, D). The mammalian POP protein consists of 710 amino acids with a calculated molecular mass of 80.7 kDa and indeed the POP antibody generated by another group detected rat and human POP at 80 kDa (Myöhänen et al., 2007). However, POP protein purified from many mammalian tissues has been reported to be 65-80 kDa (Welches et al., 1993), suggesting that the molecular mass of POP might be different between species or tissue types. Alternatively, some post-translational modifications might affect the electromobility or even the difference of marker proteins might result in the difference of the calculated molecular mass. In any case, because we could confirm the specificity of the detected band by

preincubation of the antibody with the purified POP, we concluded that the antibody specifically recognized the mouse POP protein at 72 kDa in our hands.

Localization of POP in the mouse placenta.

We investigated the localization of POP mRNA and protein in the developing mouse placenta. Using immunohistochemistry, we determined many cell types by morphology, but using *in situ* hybridization, we could not do so because the cell morphology seemed to be modified in our cryosections, for unknown reasons. While we observed strong POP immunoreactivity in spongiotrophoblast cells and four subtypes of TGCs at E16.5 and E18.5 and in other labyrinthine cells besides those at E11.5 (Figs. 4, 5), we could only identify the spongiotrophoblast, P-TGC, and S-TGC by *in situ* hybridization (Fig. 2). Nevertheless, the two data sets of the POP mRNA and protein localization are similar in that 1) spongiotrophoblast cells and P-TGCs were strongly stained at all the stages examined, 2) in the labyrinth, most cells were strongly stained before E12.5 but only TGCs were thereafter, and 3) the decidual cell was weakly stained at all the stages. These indicate that the localization of POP mRNA and protein was generally consistent with each other. It is assumed that POP is strongly expressed in the spongiotrophoblast cell and all subtypes of TGCs at E10.5-E18.5 while in the labyrinth most cells express POP at E10.5 and E11.5 but the strong expression is maintained only in the S-TGC and C-TGC after that.

An interesting finding was that POP localization changed at E12.5 in the placenta. POP was presumably down-regulated in the labyrinthine cells other than TGCs such as syncytiotrophoblast and fetal vascular endothelial cells. This suggests that POP in these cells have distinct roles from POP in other cells and is involved in some events taking place around E10-E12. For example, POP might degrade some peptides that are present only around these stages. It might also be related to differentiation of some placental cells including the syncytiotrophoblast (Rossant and Cross, 2001) or play some role in the establishment of fetal-maternal connection (Adamson et al., 2002). In contrast, POP in the

spongiotrophoblast and TGCs might be involved in the secretion of hormones and growth factors because POP was suggested to control protein secretion in human glioma cells (Schulz et al., 2005). Alternatively, POP might participate in the processing of hormones and growth factors that the spongiotrophoblast and TGCs secrete. Considering that the overall POP activity increased during the placental development (Fig. 3A), more POP activity might be required in the spongiotrophoblast and TGCs at later gestation.

To reveal the physiological role of POP in mouse development, the identification of physiological substrates is of great importance. The only peptide proven to be an *in vivo* substrate of POP is α -MSH in the mouse pituitary (Perroud et al., 2009) and it is actually known to be present in the placenta (Krieger, 1982). In addition, some proline-containing bioactive peptides in the placenta, such as substance P, angiotensin II, and oxytocin, could be substrates of POP (Gimpl et al., 2001; Marzioni et al., 2005; Walther et al., 2008). Taking into account that POP is the only enzyme capable of hydrolyzing a peptide containing proline residues, it should be indispensable for its processing or degradation. However, POP-deficient mice reported by two groups seem to be normal in terms of reproduction and development (Di Daniel et al., 2009; Warden et al., 2009), indicating that the accumulation of proline-containing peptides was not toxic to murine cells. This suggests that POP may not be very important for normal reproduction and development and it may instead play an essential role in disease prevention or stress response. More detailed analyses of the knockout mice or other strategies will be required to reveal the POP's role in reproduction and development.

Subcellular distribution of POP.

We have also assessed subcellular localization of POP and found that POP was associated with the cytoplasm and membrane in the placenta. This was based on the observation that there was no POP-immunoreactivity in the nuclei of any placental cells (Fig. 4, 5), and that no POP protein signals and no enzymatic activities were detected in the placental nuclear fractions prepared by two different methods

(Fig. 6). Although we can not completely rule out the possibility that a few placental cells contain the nuclear POP or many placental cells contain a very low level of POP in the nuclei, the results indicate that POP is predominantly localized to the cytoplasm and membrane in the mouse placenta.

Several immunohistochemical studies reported the subcellular distribution of POP and showed that in addition to the cytoplasm, POP was localized to the membrane of neurons and to the nucleus in some cultured cells and peripheral tissues (Myöhänen et al., 2008c; Schulz et al., 2005). More detailed studies reported that POP was associated with microtubules in the perinuclear cytoplasm in glioma cells (Schulz et al., 2005) and was attached to rough endoplasmic reticulum and Golgi apparatus in the rat brain (Myöhänen et al., 2008b). These data indicate that the subcellular distribution of POP is different among tissues and cells and suggest that POP has distinct roles in various tissues and cells.

It is notable that POP is not localized to the nucleus in the developing mouse placenta because the nuclear POP is thought to be involved in the regulation of cell proliferation and differentiation. This role of POP was first suggested by the finding that a specific POP inhibitor, ZTTA, inhibited DNA synthesis in the cultured cells of flesh fly and mouse and POP was localized to the nuclei in the cells (Ishino et al., 1998; Ohtsuki et al., 1997). Some of the recent studies also support this function by showing that POP was localized to the nucleus in proliferating or differentiating cells (Hannula et al., 2010; Moreno-Baylach et al., 2008). However, no particular mechanisms have yet been suggested, so it may also be possible that the cytoplasmic and membrane-associated POP could participate in cell cycle regulation. In fact, many proteins controlling the cell cycle are known to be localized to the cytoplasm although the proteins involved in DNA synthesis are usually localized to the nucleus (Besson et al., 2008; Kahl and Means, 2003; Sclafani and Holzen, 2007; Wilkinson and Millar, 2000). In case of the mouse placenta, the cytoplasmic POP may play some role in cell cycle regulation, for example, by processing or interacting with other proteins involved in the cell cycle. Alternatively, the mouse placental POP may not even be involved in cell proliferation and have other roles.

1 Enzymatic activity of cytoplasmic and membrane-associated POP.

2
3 It is interesting that the cytoplasmic POP had a higher enzymatic activity than the
4 membrane-associated form, which is consistent with previous reports (Agirregoitia et al., 2003; Irazusta
5 et al., 2002; Tenorio-Laranga et al., 2008). The cytoplasmic POP was found in every placental cell by
6 immunohistochemistry, suggesting that it has a common function to many cells. The involvement in
7 intracellular protein degradation is one possibility. In this case, high POP activity is probably necessary
8 because there are many proline-containing peptides inside the cell and POP is the only enzyme to degrade
9 them. In contrast, the membrane-associated POP may have different roles. In our current protocol, the
10 membrane fraction could contain not only the plasma membrane but also other membranes such as the
11 endoplasmic reticulum and Golgi apparatus, so it could function in either intracellular or extracellular
12 environment. Considering that a previous study found POP localized to intracellular membranes rather
13 than the plasma membrane in neurons (Myöhänen et al., 2008b), and that we did not observe any strong
14 POP immunoreactivity in the plasma membrane, the membrane form of POP is more likely to function
15 inside the cell. Because intracellular POP has been reported to interact with other proteins and be able to
16 function without its peptidase activity (Di Daniel et al., 2009; Schulz et al., 2005), the placental
17 membrane POP may work irrespective of its enzymatic activity. If the membrane POP works
18 extracellularly, it could directly contact maternal blood in some TGCs and might process or digest
19 bioactive peptides in the blood. The lower POP activity in the membrane fraction might be a result of the
20 existence of various types of membrane POP possessing different activities. Further analysis will be
21 required for revealing the functions of the two forms of POP in different placental cells.

22
23 In conclusion, this work analyzed the temporal and spatial POP expression in the mouse placenta.
24 We determined the cell type expressing POP and found that the localization of POP becomes restricted to
25 the spongiotrophoblast cells and TGCs throughout placental development. We also found that the

placental POP was associated with the cytoplasm and membrane. These results suggest that the distinct forms of POP have different roles in various placental cells.

Acknowledgements

We thank Dr. Hiroshi Kimura (Osaka University) for kindly gifting the antibody for histone H3. We also thank Dr. Katsueki Ogiwara (Hokkaido University) for helpful technical advice and critical reading of the manuscript. S.M. is a recipient of SUNBOR scholarship from SUNTORY Institute for Bioorganic Research, Japan. This work was supported by Grants-in-aid for Scientific Research 19770048 and 21770068 (A.P.K.) from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Figure Legends

Fig. 1. Northern blot analysis of POP in various mouse tissues. Total RNA was prepared from the indicated 16 mouse tissues and twenty micrograms of the RNA was electrophoresed and blotted to a nylon membrane. The blot was hybridized with a ³²P-labeled mouse POP cDNA probe and the signals were detected by autoradiography. The electrophoretic image of 28S and 18S ribosomal RNAs showed that a similar amount of total RNA was used among these tissues.

Fig. 2. Localization of POP mRNA in the mouse placenta. (A) Placentas were collected from pregnant mice on the indicated embryonic days. Four continuous sections (10 μm) were prepared for each placenta and hybridized with digoxigenin-labeled sense or antisense probes for POP or Flt1. The signals were detected by an alkaline phosphatase reaction with the nitroblue tetrazolium/5-bromo-4-chloro-3-indolyl

phosphate substrate. The Flt1 probe was used as a marker gene for the spongiotrophoblast cell. Probes used are indicated on the left of the images. High POP mRNA expression was observed in the spongiotrophoblast of the junctional zone and the labyrinth layer at E10.5 and E11.5 and only in the spongiotrophoblast thereafter. Note that the POP signal is not very strong in some sections due to the difference of the staining time. The scale bar represents 1 mm. Jz, junctional zone; La, labyrinth; Md, maternal decidua. (B) Enlarged images of the boxed regions of E11.5 and E15.5 placentas in A are shown at right. Each image represents the labyrinth and the junctional zone, respectively. To show the morphology of each placental region, images with hematoxylin and eosin staining (HE staining) are also provided at left. While most cells were stained in the labyrinth at E11.5, only S-TGC was positive in the E15.5 placenta. P-TGC, spongiotrophoblast cells, and decidual cells were positive for the POP mRNA signal at both stages. The scale bar represents 50 μ m. Md, maternal decidua; P-TGC, parietal-trophoblast giant cell; SpT, spongiotrophoblast; S-TGC, sinusoidal-trophoblast giant cell.

Fig. 3. POP protein expression in the mouse placenta. (A) Placental POP activity during gestation. Soluble tissue extracts from placentas (E10.5-E18.5) were prepared and specific POP activity toward Sac-Gly-Pro-Leu-Gly-Pro-MCA was measured. The enzymatic reaction was performed at 37°C for 20 min. The activity was expressed as the amount of AMC released per minute per mg protein under the condition. The data are shown as the average $\pm$ SD from six independent experiments with three tissues and analyzed by one-way ANOVA followed by Tukey's *post hoc* test. $n=6$; $F=14.59$; **, $P<0.01$ compared to E10.5. (B) Confirmation of the specificity of the POP antibody generated in this study. Western blot analysis was conducted with soluble extracts of the mouse placenta (E18.5) and brain as well as the purified recombinant POP (rPOP) containing 52 extra amino acids (+ 52 a.a.). The samples were separated by SDS-PAGE with an 8% gel and blotted to a PVDF membrane. After the blocking with Block Ace and normal rabbit serum sequentially, the membrane was incubated with the purified anti-POP antibody (3 lanes at left). The membranes were then incubated with horseradish peroxidase conjugated

secondary antibody and the signals were developed using an Immobilon Western Chemiluminescent HRP Substrate. The experiment was also performed by using the POP antibody preincubated with the rPOP and this resulted in the complete elimination of the POP band (Pre-absorbed, 3 lanes at right). β -actin was used as an internal control. Positions of molecular marker bands are indicated at left. (C, D) Western blot analysis of POP in various stages of mouse placentas. Western blot was conducted as in B using soluble placental extracts (E10.5-E18.5). We repeated the experiment three times, measured the intensity of each band using the Image J program, and normalized the POP signal to β -actin. The resulting graph is shown in C and a representative Western result is indicated in D. The data are shown as the average $\pm$ SD and analyzed by one-way ANOVA followed by Tukey's *post hoc* test. $n=3$; $F=0.36$.

Fig. 4. Immunohistochemistry of POP in the E11.5 placenta. The placenta was fixed in Bouin's solution, embedded in paraffin, and sectioned at 6 μ m. The slides were dewaxed, boiled in 10 mM citric acid buffer, and treated with 2.25% H_2O_2 . After the blocking with Block Ace followed by normal rabbit serum, the slides were incubated with the purified anti-POP polyclonal antibody and then with HRP conjugated secondary antibody. The signals were developed using AEC Peroxidase Substrate kit. POP immunoreactivity is indicated by red color. Images before (A, C, F) and after counter staining with Carazzi's hematoxylin (D, F) are shown. Three layers are outlined by dashed lines in A. Panels A and B are pictures with low magnification and B represents a control section treated with the primary antibody, which was preincubated with the recombinant POP protein, showing no positive signals. Magnified images of the junctional zone and maternal decidua (C, D) and the labyrinth layer (E, F) are indicated. The scale bar represents 200 μ m in A and B and 50 μ m in the other pictures. Al, allantois; Jz, junctional zone; La, labyrinth; Md, maternal decidua; P-TGC, parietal TGC; SpT, spongiotrophoblast cell; S-TGC, sinusoidal TGC.

Fig. 5. Immunohistochemistry of POP in the E16.5 (A-L) and E18.5 placentas (M-X).

Immunohistochemistry was performed as in Fig. 4. POP immunoreactivity is indicated by red color. Images before (A, C, E, G, I, K, M, O, Q, S, U, W) and after counter staining with Carazzi's hematoxylin (D, F, H, J, L, P, R, T, V, X) are shown. Three layers are outlined by dashed lines in A, B, M, and N and these panels are pictures with low magnification. B and N indicate control sections treated with the primary antibody, which was preincubated with the recombinant POP protein, showing no positive signals. Magnified images of the junctional zone (C, D, O-R) and the labyrinth layer (E-H, S-V) are indicated. In the E16.5 placenta, the glycogen trophoblast cell and the allantois are further enlarged in I-L. In the E18.5 placenta, we could also identify SpA-TGC (W, X). The scale bar represents 200 μ m in A, E, I, and M and 50 μ m in the other pictures. Al, allantois; C, canal lumen; C-TGC, canal-associated TGC; GlyT, glycogen trophoblast cell; Jz, junctional zone; La, labyrinth; Md, maternal decidua; P-TGC, parietal TGC; SpA, spiral artery lumen; SpA-TGC; spiral artery-associated TGC; S-TGC, sinusoidal TGC; SpT, spongiotrophoblast cell.

Fig. 6. Subcellular distribution of POP in the mouse placenta. (A) The cytoplasmic and membrane subfraction (C+M) were separated from the nucleus (N) using E10.5 and E15.5 placentas. Specific POP activity of each fraction was measured as in Fig. 3A but the enzymatic reaction was performed for 60 min. The data are shown as the average $\pm$ SD from six independent experiments with three tissues and analyzed by Student's *t* test. $n=6$; **, $P < 0.01$ compared with N fraction of each stage of placenta. (B) Western blot analysis was performed as in Fig. 3B using the C+M and N fractions prepared in A. (C) The extracts from E11.5 and E16.5 placentas were fractionated into cytoplasmic (C), membrane (M), and nuclear (N) subfractions. The enzymatic activity assay was conducted as in A. The enzyme activity assay was conducted independently six times with three tissues. The data were analyzed by one-way ANOVA followed by Tukey's *post hoc* test. $n=6$; $F=113.12$ and 454.72 in the E11.5 and E16.5 placenta, respectively; **, $P < 0.01$ compared with N fraction of each placenta. (D) Western blot analysis was repeated three times and a representative result is shown. The intensity of each band was measured by

1 using Image J program and the POP signal was normalized to β -actin and indicated as a graph. The
2 antibodies against histone H3 and connexin-43 were used as markers of the nucleus and plasma
3 membrane, respectively. A non-specific band was somehow detected just below the connexin-43 band in
4 the E11.5 placenta. The data are shown as the average $\pm$ SD from three independent experiments with two
5 tissues and analyzed by one-way ANOVA followed by Tukey's *post hoc* test. $n=3$; $F=9.07$ and 14.48 in
6 the E11.5 and E16.5 placenta, respectively; *, $P<0.05$ and **, $P<0.01$ compared with N fraction of each
7 placenta.

Table 1

POP expression summary of the immunohistochemistry.

	E11.5	E16.5	E18.5
maternal decidua			
decidual cell	++	++	++
SpA-TGC	ND	ND	+++
P-TGC	+++	+++	+++
junctional zone			
spongiotrophoblast cell	+++	+++	+++
glycogen trophoblast cell	*	+	+
labyrinth layer			
S-TGC	+++	+++	+++
C-TGC	ND	+++	+++
allantois	-	-	-
other cells	+++	+/-**	+/-**

*, Glycogen trophoblast cells are not present in E11.5 placenta.

**, Most cells are negative, but some cells may have weak POP-immunoreactivity.

SpA-TGC, spiral artery-associated TGC; P-TGC, parietal TGC; S-TGC, sinusoidal TGC; C-TGC, canal-associated TGC; ND, not determined
