Abstract
MRL/MpJ (MRL) is a mouse model for autoimmune disease and develops ovarian cysts with age. The ovarian cysts originate from the rete ovarii, which is considered to be the remnant of fetal mesonephric tubules. In a previous study, we analyzed the genetic background of ovarian cysts by using backcross progenies between MRL and C57BL/6N (B6) mice. By interval mapping, suggestive linkages were detected on several chromosomes (Chrs), and a significant linkage on Chr 14 was designated as MRL Rete Ovarian Cyst (mroc).

In the present study, which evaluated 113 F2 intercross progenies, a significant linkage appeared on Chr 6 at the marker position D6Mit188 (likelihood ratio statistic = 18.5). In particular, the peak regions of Chrs 6 and 14, which contain major causative loci by backcross analysis, showed close reverse interaction. From these results, a locus on Chr 6 was identified as mroc2, the second major locus associated with ovarian cyst formation in MRL mice.

Key words: cystic rete ovarii, MRL/MpJ mice, mroc2, QTL analysis, rete ovarii

Introduction
In humans and animals, ovarian cysts are major causes of female reproductive dysfunctions. They are derived from several components of the ovary, such as ovarian surface epithelium, follicles, corpus luteum, and rete ovarii.2,16) In veterinary medicine, ovarian disorders, including cystic changes, cause economic loss by affecting the fertility of farm animals such as cattle, sheep, and swine.16)

The rete ovarii is homologous to the male rete testis. It is considered to be the remnant of mesonephric tubules and is composed of mesenchymal cells that have migrated from the mesonephros to the embryonic gonad.6,24–26) While...
In the present study, we analyzed F2 intercross progenies to obtain more detailed information about candidate QTLs related to the development of ovarian cysts in MRL mice. Comprehensive and accurate QTL analysis using both backcross and F2 progenies is fundamental for identifying the genes responsible for the development of rete ovarian cysts. These results would provide novel genetic information about the pathogenesis of ovarian disease in human and veterinary reproductive medicine.

Materials and Methods

Animals: Mouse MRL and B6 strains were purchased from Japan SLC Inc. (Hamamatsu, Japan), and F1 progenies from these were generated in our laboratory. A total of 113 F2 progenies were generated by an MRL × B6 cross between F1 mice of both sexes. Some F1 progenies were mated with MRL mice to produce 213 MRL × [MRL × B6] F1 backcross progenies as previously described. These animals were maintained in specific pathogen-free conditions with a room temperature of 22°C ± 4°C, relative humidity of 55% ± 20%, and a 12-h light and dark cycle in the animal facility of the Graduate School of Veterinary Medicine, Hokkaido University. The mice were allowed free access to water and rodent food in pellet form. The mice were housed in an animal facility approved by the Association for Assessment and Accreditation of Laboratory Animal Care, and the project was approved by the Animal Experiment Committee of the Graduate School of Veterinary Medicine, Hokkaido University.

Phenotyping: The phenotyping of ovarian cystic change was performed according to our previous study. Briefly, ovaries of F2 progenies were collected at 8 months of age, fixed with Bouin’s solution overnight, processed through graded alcohol, and embedded in paraffin by a routine procedure. Serial sections 3-μm-thick by 30 μm
intervals with bilateral ovaries were cut and stained with hematoxylin and eosin by standard procedures. Only the section containing the biggest cystic rete ovarii was chosen for phenotype evaluation, photographed with a digital camera, and measured by ImageJ (NIH, http://www.nih.gov/ij/). Because we had already confirmed that the circumference of the rete ovarii reflected the severity of ovarian cysts, these values were used as a quantitative trait in QTL analysis. When calculating the rete ovarii circumference in all mice, the F2 progenies with both larger values than the average B6 value and flattened epithelia were considered to show cystic changes.

Statistical analysis: The phenotype values of MRL, B6, and their progenies were evaluated by the nonparametric Kruskal-Wallis test (Schefe’s method) (Fig. 1c).

Genotyping: Genomic DNA was extracted from the spleen with a standard protocol and applied to a genome-wide scan analysis based on polymerase chain reaction (PCR), using 98 polymorphic microsatellite markers (Table 1). For 0.2- to 40.0-cM intervals (average = 15.1 cM), primer pairs of microsatellite markers were selected from the database at Mouse Genome Informatics (http://www.informatics.jax.org/).

PCR was carried out on a PCR thermal cycler (iCycler; Bio-Rad, Madison, WI, USA) with a cycling sequence of 94°C for 2 min (1 cycle) followed by 40 cycles consisting of denaturation at 94°C for 40 s, primer annealing at 58°C for 30 s, and extension at 72°C for 30 s. Taq DNA polymerase and buffers were purchased from Promega (Madison, WI, USA). The amplified samples were electrophoresed in 2% NuSieve 3:1 Agarose Gel (Cambrex Bio Science Rockland Inc., Rockland, ME, USA) or Agarose 3:1 (AMRESCO Inc., Solon, OH, USA), stained with ethidium bromide, and photographed under an ultraviolet lamp.

Genomic linkage and statistical analysis: Before whole-genome scanning, 6 F2 mice of high trait in ascending order of rete ovarii circumference (> 7,000 μm) were tested by chi-square (χ²) analysis to identify the causative chromosomes. To identify the QTLs of ovarian cysts, the data of the trait score and genotyping were analyzed by MapManager QTxb20. The permutation tests were performed in 1-cM steps for 10,000 permutations to determine the statistically suggestive, significant, and very significant levels. Final results of interval mapping were considered to be suggestive for an LRS of 9.2, significant for an LRS of 17.2, and highly significant for an LRS of 28.8.

Among whole-genomic-locus-coded microsatellite markers, the interactive locus throughout the genome was analyzed by χ² statistics by MapManager QTxb20. The genotype and phenotype values of the interactive locus were investigated in detail and compared with those of the significant locus on Chr 6 by F2 QTL analysis.

Results

Histological features and distribution of ovarian cyst sizes in B6 and MRL progenies

Fig. 1 shows the histology and appearance of dilated rete ovarii in MRL, B6, F1, and F2 progenies. From 113 F2 progenies, 31 mice showed cystic changes in the rete ovarii according to our histological criteria. However, the circumference of rete ovarii varied among these mice (Fig. 1a and b). The circumferences of rete ovarii in MRL and B6 mice and their progenies were compared as shown in Fig. 1c. The average values of F2 progenies tended to be smaller than those of backcross progenies and larger than those of F1 progenies (Fig. 1c). In Fig. 1d, the individual traits of F2 progenies (n = 113) were arranged by the circumference of rete ovarii and compared with those of backcross progenies (n = 213). The trait distribution curve of F2 progenies was sharper than that of backcross progenies, and the maximum circumferences of
QTL analysis of ovarian cysts in MRL mice

(32.53 cM) on Chr 6 showed the most significant linkage to cystic changes in rete ovarii (Table 2).

In QTL analysis, the highest linkage above the significant level (LRS > 17.2) was detected only in Chr 6, and suggestive linkages (9.2 < LRS < 17.2) were not found in any chromosomes (Fig. 2a). Linkage details are shown in Fig. 2b. The loci at the D6Mit188 (32.53 cM) marker position showed the highest linkage (LRS =

the rete ovarii of F2 progenies were lower than those of backcross progenies.

Genetic analysis of ovarian cysts in F2 progenies

To clarify the relationships between genotypes of F2 progenies and each chromosome locus, the \( \chi^2 \) test was performed using 6 selected progenies showing large rete ovarii circumferences in ascending order. The marker position D6Mit188 (32.53 cM) on Chr 6 showed the most significant linkage to cystic changes in rete ovarii (Table 2).
Fig. 1. Histological observation of cystic changes in murine rete ovarii of 8-month-old F2 progenies from crosses between B6 and MRL. (a) A small rete ovarian cyst (arrow) can be seen localized near the hilus. (b) Remarkable expansion of rete ovarii (asterisk) can be observed. Bars = 200 μm. (c) Average of ovarian cyst sizes in MRL, B6, (MRL × B6) F1, F2, and backcross progenies (mean ± S.E.) were evaluated by the nonparametric Kruskal-Wallis test (Scheffe’s method). (*P < 0.0001, **P = 0.003). (d) Distributions of circumferences of rete ovarii in 113 F2 and 213 backcross progenies.

18.5), and D6Mit243 (32.37 cM) and D6Mit323 (37.75 cM) beside the peak region showed suggestive linkages to the circumference of ovarian cysts. From these results, we defined a significant locus around a suggestive locus (D6Mit243–D6Mit323: 32.27–37.75 cM) as a susceptibility locus of ovarian cyst development (MRL Rete Ovarian Cyst 2 [mroc2]).

Furthermore, the loci of D1Mit191, D7Mit82, D12Mit185, D13Mit13, D14Mit37, D14Mit193, D14Mit265, and D17Mit221 interacted with D6Mit188 in mroc2, showing high P values, according to the analysis by MapManager QTXb20 (Table 3). Above all, interaction analysis using F2 generations showed that the broad region on Chr 14 (D14Mit37, D14Mit193, and D14Mit265: 33.21–50.90 cM) containing the major locus mroc was closely related with D6Mit188 in mroc2. Other interactive loci not showing direct effects on the phenotype of ovarian cysts were interpreted as indirect modifier factors in the environmental background in F2 progenies.

Discussion

In this study, we analyzed the genetic locus associated with the development of MRL ovarian cysts. Our previous study using backcross progenies between MRL and B6 mice revealed that the development of ovarian cysts is regulated by polygenic factors on autosomes. Further investigation of genetic loci with significant effects on ovarian cyst development will contribute to a deeper understanding of the genetic background of MRL ovarian cysts.
QTL analysis of ovarian cysts in MRL mice

To identify the genetic loci affecting the dilations of rete ovarii, we performed QTL analysis using F2 progenies and clarified that only marker positions from D6Mit243 to D6Mit323 (32.27–37.75 cM) on Chr 6 showed high linkage to this phenotype. In particular, D6Mit188 (32.53 cM) exceeded the significant level.

Furthermore, F1 progenies composed of MRL/B6 heterozygotes showed smaller and larger rete ovarii than F2 and backcross progenies and B6 progenies, respectively. From these findings, we considered that the dilations of rete ovarii are promoted by both MRL-derived recessive and dominant factors. In addition to the MRL genetic background, we could not eliminate the possibility that B6-derived genetic factors inhibited the rete ovarii dilations.

Chr = Chromosome, M = MRL homozygous, B = B6 heterozygous, H/B = Heterozygous. ※Degrees of freedom = 2
which were found in our previous study, we named the QTL on Chr 6 (32.27–37.75 cM) in F2 analysis as \textit{mroc2}. \textit{mroc2} was reported to contain ovarian teratoma susceptibility loci (\textit{Ots1}) in (B6 × LT/Sv) F2 analysis of Chr 6 (32.53 cM).\textsuperscript{13} Furthermore, transforming growth factor alpha, which regulates the development and growth of the female reproductive system, is localized in the \textit{mroc2} region (Chr 6, 37.62 cM)\textsuperscript{7}. To determine the major candidate gene affecting dilations of MRL rete ovarii, further studies focusing on qualitative and quantitative analyses of these genes on \textit{mroc2} are required.

On the other hand, a contradiction exists,
QTL analysis of ovarian cysts in MRL mice

The severity of this polygenic phenotype. The complex interactions among genetic backgrounds through particular strain combinations cannot be easily explained; however, our results of both F2 and backcross progenies implicate the mechanisms of modifying interactions.

In summary, we performed genome-wide screenings for spontaneous ovarian cysts in MRL mice. Our results indicate that the specific locus on Chr 6, named mroc2, is a crucial factor triggering ovarian cysts in MRL mice. Based on the fact that the QTL detected in backcross analysis did not reappear in F2 analysis, we conclude that ovarian cysts in MRL mice develop from a summation of complex genetic interactions.

especially in terms of cyst severity, between F2 and backcross analyses of mroc and mroc2 genotypes. Briefly, the F2 progenies having significantly larger ovarian cysts simultaneously showed MRL/MRL homozygosity on mroc2 and B6/B6 homozygosity or MRL/B6 heterozygosity on mroc (Table 2). However, the backcross progenies having significantly larger rete ovarii showed MRL/B6 heterozygosity on mroc2 and MRL/MRL homozygosity on mroc.\(^\text{14}\) Although the present study could not clarify this genetic contradiction between F2 and backcross progenies, QTL and interaction analyses provided some interesting data. The loci on Chrs 1, 7, 12, 13, 14, and 17 showed significant interactions with Chr 6 (32.53 cM) on mroc2, and Chr 7 also showed significant interactions with Chr 6 (32.27 cM and 37.75 cM) on mroc2. Importantly, D14Mit265 (50.90 cM), D14Mit193 (37.26 cM), and D14Mit37 (33.21 cM), which showed significant interactions with D6Mit188 (Chr 6; 32.53 cM), contained mroc.\(^\text{14}\) Furthermore, there was a possibility that these loci might directly or indirectly interact with each other, including mroc2. From these findings, we considered that mroc2 in F2 progenies was affected by several autosomal loci, including mroc, and that the potency and balance of these genotypes determined the severity of this polygenic phenotype. The complex interactions among genetic backgrounds through particular strain combinations cannot be easily explained; however, our results of both F2 and backcross progenies implicate the mechanisms of modifying interactions.\(^\text{8,9,12,18,19}\)

In summary, we performed genome-wide screenings for spontaneous ovarian cysts in MRL mice. Our results indicate that the specific locus on Chr 6, named mroc2, is a crucial factor triggering ovarian cysts in MRL mice. Based on the fact that the QTL detected in backcross analysis did not reappear in F2 analysis, we conclude that ovarian cysts in MRL mice develop from a summation of complex genetic interactions.
