ABSTRACT

A new Real-Time PCR assay was successfully developed using a TaqMan® fluorescence probe for specific detection and enumeration of a novel bacterium, *Lactobacillus thermotolerans*, in chicken feces. The specific primers and probe were designed based on the 16S rRNA gene of *L. thermotolerans* sequences and their sequences were compared to those of all available 16S rRNA genes in GenBank. The assay, targeting 16S rRNA gene, was evaluated using DNA from a pure culture of *L. thermotolerans*, DNA from closely related bacteria, *Lactobacillus mucosae* DSM 13345ᵀ; *Lactobacillus fermentum* JCM 1173ᵀ and DNA from other lactic acid bacteria in quantitative experiments. Serial dilutions of *L. thermotolerans* DNA were used as an external standard for calibration. The minimum detection limit of this technique was $1.84 \times 10^3$ cells/ml of pure culture of *L. thermotolerans*. The assay was then applied to chicken feces in two different trials. In the first trial, the cell population was $10^4$ cells/g feces on d4 and $10^5$ cells/g feces on d11-18. However, cell population of $10^6$ to $10^7$ cells/g feces were detected in the second trial. The total bacterial count, measured by 4', 6-diamidino-2-phenylindole (DAPI) staining, was approximately $10^{11}$ cells/g feces. These results suggest that *L. thermotolerans* is in general distributed as a
normal member of the chicken gut microbiota, although it is present in relatively
low numbers in the feces.

Key words: *Lactobacillus thermotolerans*, Real-Time PCR, Chicken feces
INTRODUCTION

Previously we have isolated *Lactobacillus thermotolerans*, a novel species, from chicken feces collected in Thailand (9). The preference of this bacterium for the chicken intestine may be due to the body temperature of chickens, 42°C (2), which corresponds to the optimum temperature for growth (42°C) of this bacterium, as determined by measurement of the specific growth rate (9).

Our current interest in *L. thermotolerans* is to characterize this bacterium ecologically in chicken intestine, since no studies have been conducted to date on the ecology of this new bacterium. Studies on the distribution and colonization of *L. thermotolerans* in different organs of gastrointestinal tract will provide a new insight in chicken intestinal microbiology. For this purpose an effective method for enumeration of this bacterium is required. The development of a molecular ecological enumeration method appears to be of particular value in the case of *L. thermotolerans*, since conventional culture methods are insufficient due to the relatively high temperature required for culturing this bacterium. Real-Time PCR offers significant advantages over other molecular enumeration techniques in terms of the speed by which assays are performed and the ability to quantify the target microbial population. Real-Time PCR has already been established as a promising tool for studies
on the composition of microbial communities in the gastrointestinal tract or
feces of humans (1, 4, 5, 12) as well as chickens (13). However, most studies
with a focus on chicken microbiota have been conducted using conventional
culture methods (6, 8, 10, 11). To the best of our knowledge, there has not yet
been a report focusing on the Real-Time monitoring of chicken lactobacilli, a
commonly used probiotic organism in the avian industry. The use of
probiotics to promote health and nutrition has attracted a great deal of
attention these days and claims have been made in this context with regard to
daily weight gain, improvement in feed conversion and resistance to disease
(3).

In this study, establishment of conditions for a Real-Time PCR assay of *L.
thermotolerans* and its successful application for monitoring population
dynamics of this bacterium in chicken feces will be described.
MATERIALS AND METHODS

Bacteria and growth conditions. The strains used in the current study are listed in Table 1. *L. thermotolerans* JCM 11425\textsuperscript{T} was cultured using mixed gas (N\textsubscript{2}: H\textsubscript{2}: CO\textsubscript{2}= 8: 1: 1) in Difco Lactobacilli MRS Broth (Becton, Dickinson and Company) at 42°C overnight, and the reference strains were grown under the same conditions, with the exception that the culture temperature was 37°C.

Chicken maintenance and sample collection. Two trials (trial 1 and trial 2) were conducted using five layer chicks (Boris Brown, one day old) in each trial in two different periods. The chicks were obtained from the Hokuren Federation of Agricultural Cooperatives (Sapporo, Japan) and were kept in an individual section of a wooden box and were reared for a period of 4 weeks for trial 1, and 3 weeks for trial 2. Chickens were maintained and handled according to the recommendations of the Ethics Committee at our institute. The animals were given commercial feed (crude protein, 200 g/kg; and energy, 2950 kcal/kg) *ad libitum* once a day. Water was available during the entire experiment. Fresh feces were collected from individual chicks on d4, 11, 18, and 27 in the case of trial 1, and on d1, 7, 14, and 21 in the case of trial 2. A
sterilized spatula was used for feces collection, and the samples were
immediately transferred to the laboratory for further use.

**DNA extraction.** The genomic DNAs were isolated from the culture
broths of *L. thermotolerans*, and reference strains used as negative controls,
and from feces using UltraClean™ Soil DNA Kit (MO BIO Laboratories, Inc.,
Solana Beach, CA), following the manufacturer's instructions. Before DNA
extraction, samples (0.1 g feces or 0.1 ml culture) were incubated with 50 µl
of lysozyme (5 mg/ml) and 15 µl of *N*-acetylmuramidase (10.2 u/µl) at 37°C
for 15 min. The quality of the extracted DNA was analyzed by electrophoresis
on 1.5% agarose gel. The DNA concentrations were measured by absorbance
at 260 nm in a Beckman DU 640 Spectrophotometer (Beckman Coulter, Inc.,
Fullerton, CA). The DNA was then used for the Real-Time PCR assay.

**Design of primers and probe.** The PCR primers and probe were designed
targeting 16S rRNA gene of *L. thermotolerans* with Primer Express™ v2.0
(Applied Biosystems, Foster City, CA), and the specificity of these sequences
was further checked against all the available data of 16S rRNA genes in
GenBank. The probe was labeled with fluorescent dye 6-carboxyfluorescein
(6-FAM) at the 5’ end, and 6-carboxytetramethylrhodamine (6-TAMRA) at the
3’ end. The sequences were 5’-TGCACAGGATTGACGTTGGT-3’, 5’-GCAGGTGCCTACGTTACT-3’ and 5’-TCCCAACGAGTGGGGACCGG-3’ for the forward primer (92F), reverse primer (157R), and TaqMan® probe (113T probe), respectively.

5' nuclease PCR assay conditions. The amplification reactions were carried out in a total volume of 50 µl, and the mixtures contained 1xTaqMan® Universal PCR Master Mix (Applied Biosystems) including 900 nM each of the *L. thermotolerans*-specific primers, a 250 nM fluorescence-labeled *L. thermotolerans*-specific probe, and 20 ng DNA for each treatment. Amplification reactions were performed on an ABI PRISM® 7000 Sequence Detection System (Applied Biosystems), and the reactions were carried out after 2 min at 50°C (activation of the uracil N-glycosylase) and 10 min at 95°C (activation of the AmpliTaq Gold DNA Polymerase), followed by 15 s at 95°C (denaturation) and 1 min at 63°C (anneal/extension) for 40 repeated cycles. Due to the positive signal of the closely related bacterium, *L. mucosae* (95% similarity), we increased the annealing temperature from 60 to 63°C. Data analysis was carried out using ABI PRISM® 7000 Sequence Detection System software v1.0 (Applied Biosystems). Each sample was analyzed in
triplicate.

**Specificity of the PCR assay.** The DNAs extracted from the pure culture of *L. thermotolerans* and the reference strains were used to test the specificity of the primer-probe set. The most closely related strains, *L. mucosae* DSM 13345<sup>T</sup> and *L. fermentum* JCM 1173<sup>T</sup>, had two mismatches in the designed probe, which enabled discrimination between strains. The discrimination of other bacterial strains from *L. thermotolerans* was carried out by evaluation of a threshold cycle (C<sub>t</sub>) or C<sub>t</sub> value. The C<sub>t</sub> was defined as the cycle at which fluorescence is significantly different from the background. Therefore, the C<sub>t</sub> value provided an accurate measure of the number of target molecules originally present in the sample. Samples of the purified DNA (20 ng) were used as the template in the Real-Time PCR assay, which was carried out according to the thermal cycling conditions and data analysis as described above. Sterilized distilled water (SDW) was used as a non-template control.

**Accuracy of the assay.** In order to test the accuracy of the assay, a 0.1 g feces sample was mixed with various amounts (50, 100, or 150 μl) of pure culture of *L. thermotolerans* (1.84x10<sup>7</sup> cells/ml); the mixture was then subjected to DNA extraction, and then the number of cells was quantitated by
Real-Time PCR. The assay was repeated twice.

**Total count of bacterial population by DAPI.** The total cell number in the pure culture (*L. thermotolerans* cells/ml) and that in the feces were counted after staining the samples with 4', 6-diamidino-2-phenylindole dihydrochloride (DAPI) n-hydrate solution (Wako Pure Chemical Industries, Ltd., Osaka, Japan) for 5 min at room temperature. The cells were examined under an Olympus BX50 microscope equipped with BX-FLA (Olympus Corporation, Tokyo, Japan). The DAPI signal was captured in ten random microscopic fields.

**RESULTS**

**Primer-probe design and specificity.** The specificity of the assay with the primer and probe combination that we developed for the detection of *L. thermotolerans* was assessed using purified genomic DNA from a target strain and the negative controls listed in Table 1. Real-Time generated *C*ₗ values of 18.5 and 34.85 (average) were yielded for our target strain and the negative controls, respectively. However, a *C*ₗ value of 34.50 was obtained for sterilized
distilled water (SDW), which corresponded to the value obtained for the negative controls (Table 1). According to the hypothesis (5) that the $C_t$ values of the negative controls and the SDW might have been due to *Escherichia coli* DNA contamination of the Taq polymerase, we repeated the assay after treatment of the Master Mix with DNase I (Promega Corporation, Madison, WI). However, even after the treatment, we were unable to remove the signal obtained with the negative control and the SDW samples.

**Calibration curve and the sensitivity of the assay.** In order to construct a calibration curve and to determine the sensitivity of both primer-probe combinations, serial dilutions of DNA prepared from the pure culture of *L. thermotolerans* ($1.84 \times 10^7$ cells/ml) were used for the PCR assay (Fig. 1). The minimum detection limit of the assay was $1.84 \times 10^3$ cells/ml of pure culture of *L. thermotolerans* ($C_t$ 32.22, while SDW was 34.50). The calibration curve was constructed by plotting the $C_t$ values (Fig. 1) against known serial dilutions of *L. thermotolerans* DNA corresponding to cell concentrations between $1.84 \times 10^3$ and $1.84 \times 10^7$ cells/ml; the resulting curve is shown in Fig. 2. Each sample was analyzed in triplicate, and the variation in the $C_t$ values of multiple replicate runs were found to be very low as indicated by standard
deviation (Fig. 2). The efficiency of the curve was excellent (above 94%), as
the correlation coefficient was 0.9974, and a slope of $\log_{10}3.4652$ was obtained.
The efficiency was calculated on the basis of 100% efficiency correspond to
slope of $\log_{10}3.32192$ (14).

**Accuracy of the assay.** In order to test the accuracy of the assay, pure
cultures of *L. thermotolerans* at volumes of 50, 100, and 150 µl containing
9.2x10^5, 1.8x10^6, and 2.8x10^6 cells (DAPI count), respectively, were added to
chicken feces (0.1 g, containing 2.1x10^5 *L. thermotolerans* cells, Real-Time
monitoring), followed by DNA extraction and quantification by Real-Time
PCR. All of the samples yielded values that were slightly high, but almost the
same cell numbers as those expected were observed (Fig. 3), thus
demonstrating correlation regression, an $R^2$ value of 0.9976. The results
obtained here suggest that the recovery of the cells from these samples was
quite accurate; therefore, this newly developed PCR method is applicable for
examination of the bacterial content in chicken feces.

**Detection of *L. thermotolerans* in chicken feces.** In Fig. 4, the cell
population of *L. thermotolerans* in the chicken feces of individual chickens in
two trials monitored by Real-Time PCR is shown. In trial 1, the cell
population of *L. thermodurans* ranged between 1.8x10³ to 9.7x10⁹ cells/g feces. In general, the chickens showed a tendency toward higher numbers of *L. thermodurans* cells until d27. In trial 2, the total *L. thermodurans* results also showed a tendency toward slow increases in some chickens from d1 to d21.

Table 2 shows the average total *L. thermodurans* count for each trial, as obtained by Real-Time PCR carried out on chicken feces samples. In trial 1, a higher number of cells (2.44x10⁹ cells/g feces) were observed on d27, as compared with those observed from d4 to d18 (10⁴ to 10⁵ cells/g feces). In trial 2, the average cell populations increased tenfold (10⁶ to 10⁷ cells/g feces) from d1 to d21. The total cell populations measured by DAPI staining were approximately 10¹¹ cells/g feces in both trials. Thus, in percentage *L. thermodurans* ranged between 9.2x10⁶ to 8.5x10¹ in trial 1, and 1.5x10⁻³ to 4.5x10⁻² for trial 2 in feces against total cells in this study.

**DISCUSSION**

Here, we developed a Real-Time PCR assay that is rapid, specific and
sensitive for the monitoring *L. thermotolerans*. The sensitivity of our method was a minimum of $1.84 \times 10^3$ cells/ml of pure culture of *L. thermotolerans*, which is rather low sensitivity as compared to the other cases where the detection limit at the level of $0 \log_{10}$ have been reported (5, 13). This was because of the unusual fluorescence signal expressed in the negative controls and SDW (Table 1) probably due to the contamination of nucleotides present in the PCR Master Mix as has previously been reported (5). Although we attempted to eliminate the signal by using DNase I, the *Ct* value remained unchanged. The specificity of primer-probe sets used in the newly developed Real-Time PCR assay for *L. thermotolerans* detection was established by discrimination between intestinal bacteria and food bacteria (Table 1). The accuracy of this Real-Time PCR assay was nonetheless demonstrated in another quantitative experiment, in which feces were mixed with a known amount of pure culture of *L. thermotolerans* for evaluation of the recovery achieved by the present assay (Fig. 3). All of the samples yielded slightly higher cell numbers than those expected, a result which may have been due to an error in the DAPI count of the added cell number in *L. thermotolerans* pure culture. It has previously been reported that phenolic compounds from plant
may bind to DNA, and thus can interfere with PCR reactions (7). The results shown in Fig. 3 clearly indicate that our new method is free from PCR inhibitors associated with the fecal samples. In fact, the possibility of an inhibition of PCR when using fecal samples from chickens reared on commercial feed is thought to be lower than that associated with PCR studies of herbivores, whose feed contains phenolic compounds originating from plant materials. Based on our results, it was concluded that the present method enabled the accurate and sensitive detection of *L. thermotolerans* cells in chicken feces. This new method thus provides a powerful tool to monitor the distribution and abundance of this bacterium in a complex microbial community.

In general, most of the chickens used in trial 1 showed an increase in the *L. thermotolerans* population in the feces samples collected from d4 to d27 (Fig. 4). These results suggest that *L. thermotolerans* colonize slowly, i.e., until the second week of life, and then rapid proliferation on d27. The average cell population of *L. thermotolerans* on d27 (Table 2) was found to be tenfold that of *L. salivarius* (10^8 cells/g feces on d40) reported previously (11) in chicken feces. In trial 2, the initial number of target cells on d1 in chicks 1 and
3 was higher than that of chickens in trial 1. Moreover, the increase in the
target strain with time tended to be slower than that of the target strain
observed in trial 1. In the present study, the two trials were conducted during
different periods of time using different batches of chicks. Moreover, the
microbiota of these chicks was not controlled by the suppliers. Therefore,
based on the present results, we were also able to conclude that *L. thermotolerans* is indeed a normal member of the microbiota of the chicken
intestine. Since the total bacterial population in chicken feces is approximately
10$^{11}$ cells/g, our results demonstrated that *L. thermotolerans* accounts for a
minor percentage of the bacterial diversity in the chicken feces (Table 2).

In conclusion, we developed a highly sensitive and specific Real-Time
PCR assay for the detection of *L. thermotolerans* present in chicken feces.
This newly developed assay was successfully applied to monitor the dynamics
of this novel bacterium in chicken feces thereby providing a powerful tool to
study the distribution and abundance of this bacterium in a complex microbial
community. The present results also demonstrated that this novel bacterium is
a normal member of the chicken intestinal microbiota.

We are currently developing fluorescent *in situ* hybridization coupled with
confocal laser scanning microscopy method to visualize epithelium surface colonization of *L. thermotolerans* in chicken gastrointestinal tract. These studies together with the enumeration of this bacterium in chicken intestine by Real-time PCR method will provide much more comprehensive knowledge about ecology of *L. thermotolerans* in chicken gastrointestinal tract.

ACKNOWLEDGMENTS

This work was done by collaboration in a Core University Program between Yamaguchi University and Kasetsart University, supported by the Scientific Cooperation Program agreed by the Japan Society for the Promotion of Science (JSPS) and the National Research Council of Thailand (NRCT). Abu Sadeque Md. Selim received a scholarship from the Ministry of Education, Culture, Sports, Science and Technology of Japan to support his studies in Japan. We would like to thank Prof. Dr. Yasuo Kobayashi, and Prof. Dr. Kozo Asano, Graduate School of Agriculture, Hokkaido University, for the critical reading of this manuscript.
