Supporting Information

ABSTRACT: Cubic and orthorhombic NaNbO₃ were fabricated to study the effects of crystal structure and electronic structure on the photocatalytic activities in detail. The samples were characterized by X-ray diffraction, field emission transmission electron microscopy, high-resolution transmission electron microscopy, UV–visible absorption spectroscopy, and X-ray photoelectron spectroscopy. The photocatalytic activities of the two phases of NaNbO₃ have been assessed by H₂ evolution from aqueous methanol solution and CO₂ photoreduction in gas phase. The photocatalytic H₂ evolution and CO₂ reduction activities over cubic NaNbO₃ were nearly twice of those over orthorhombic NaNbO₃. The first-principles calculation reveals that the higher activity over cubic NaNbO₃ can be attributed to its unique electronic structure, which is beneficial for electron excitation and transfer.

INTRODUCTION

As the fossil fuels have limitations in availability, a new source that can provide abundant and maintainable energy must be developed.^{1,2} For the past decades, photocatalysis has been developed as a candidate that can supply a renewable, unlimited, and environmentally friendly energy source to solve the energy crisis.^{3,4} The investigations on photocatalytic reaction mechanisms,^{5–7} energy-band structure engineering (including the optimization of crystal structure and the modulation of band energy levels),^{8–10} and morphology control^{11–15} have been carried out to enhance the photocatalytic efficiency. Generally, to study the relationship between crystal structure and electronic structure is helpful to understand the process of photogenerated carrier excitation and transfer. Up to now, the relevant studies have been performed on the TiO₂, CdS, BiVO₄, and AgGaO₂ with different crystal structures.^{16–19} Among intensively studied photocatalysts, the materials with perovskite and multilayered perovskite structures have received considerable attention.^{20–24} However, the report about the influence of crystallographic symmetry on photogenerated carrier excitation and transfer in the perovskite-structured photocatalysts is still limited.

NaNbO₃ is nontoxic, highly stable, and with a typical perovskite structure and thus attracts extensive attention in the field of photocatalysis. Many investigations have proved that NaNbO₃

is a high-efficient photocatalyst for H₂ generation.^{25–29} Under the irradiation of high-pressure mercury lamp, H₂O can be reduced into H₂ with quite high efficiency over NaNbO₃ nanoparticles.²⁹ Nanofiber-structured NaNbO₃ was also verified to be useful to split pure water and reduce CO₂ to CH₄.³⁰ Moreover, NaNbO₃ normally belongs to the orthorhombic system at room temperature and exhibits an unusual complex sequence of temperature-, pressure-, and particle-size-driven phase transitions.^{31–35} When the temperature ranges from room temperature to 1000 K, there are several other phases of NaNbO₃ existing, such as tetragonal and cubic structures.³⁶ All of them, cubic, tetragonal, and orthorhombic NaNbO₃, are constructed from a basic perovskite unit. However, to the best of our knowledge, all the reported photocatalytic measurements were carried out over the common orthorhombic NaNbO₃ and no measurement has been done over the other phases of NaNbO₃. Fabricating the NaNbO₃ with different crystal structures will help us to understand the influence of the crystallographic symmetry in the perovskite structure on the electronic structures and photocatalytic properties. Hence, in this work, cubic NaNbO₃ (c-NaNbO₃) and orthorhombic NaNbO₃ (o-NaNbO₃) were selectively synthesized.

The photocatalytic properties of these materials were characterized using the photocatalytic H₂ evolution and CO₂ photoreduction under UV–visible light irradiation. Detailed studies on the electronic structures were performed to understand the difference of photocatalytic activity between the *c*-NaNbO₃ and *o*-NaNbO₃.

EXPERIMENTAL SECTION

Material Preparation. The *c*-NaNbO₃ was synthesized via a typical furfural alcohol derived polymerization–oxidation (FAPO) process.³⁷ First, 1.0 g of (C₂H₅O)₃Nb and 0.24 g of C₂H₅ONa were added into 10 mL of 2-methoxyethanol and stirred at room temperature to form a clear colloid. After that, 2.5 g of P-123 (*M_w* = 5800) dissolved in 30 mL of furfuryl alcohol was added. Next, the mixture was stirred for 30 min and then heated to 95 °C with a rate of 1 °C·min⁻¹ and maintained at this temperature for 120 h in air to form a black solid polymer. Finally, the black solid was oxidized in air at 600 °C for 5 h, and a white powder product was obtained. To synthesize *o*-NaNbO₃ by a polymerized complex (PC) method,²⁹ 1.0 g of NbCl₅ and 0.20 g of Na₂CO₃ were added into 10 mL of ethanol and stirred at room temperature to form a clear colloid. This colloid was then added into 50 mL of ethanol solution containing 12.0 g of citric acid and 2.0 mL of ethylene glycol. After it was stirred for 30 min, the mixture was heated to 120 °C with a rate of 1 °C·min⁻¹ and maintained at this temperature for 20 h in air for polymerization. Finally, the polymer was oxidized in air at 600 °C for 2 h, and a white powder product was obtained.

Sample Characterization. The crystal structure of NaNbO₃ powder was determined with an X-ray diffractometer (Rint-2000, Rigaku Co., Japan) with Cu K α radiation. The diffuse reflection spectra were measured with an integrating sphere equipped UV–visible recording spectrophotometer (UV-2500PC, Shimadzu Co., Japan) using BaSO₄ as a reference, and the optical absorptions were converted from the reflection spectra according to the Kubelka–Munk equation. The specific surface areas were determined with a surface-area analyzer (BEL Sorp-II mini, BEL Japan Co., Japan) by the Brunauer–Emmett–Teller (BET) method. Transmission electron microscopy images and high-resolution electron microscopy images were recorded with a field emission transmission electron microscope (2100F, JEOL Co., Japan) operated at 200 kV. X-ray photoelectron spectroscopy (XPS) experiments were performed in type Theta probe (Thermo Fisher Co.) using monochromatized Al K α at $h\nu = 1486.6$ eV, and the peak positions were internally referenced to the C 1s peak at 284.6 eV.

Photocatalytic H₂ Evolution. The H₂ evolution experiments were carried out in a gas closed circulation system. The NaNbO₃ powder (0.3 g) was dispersed by using a magnetic stirrer in CH₃OH aqueous solution (220 mL of distilled water + 50 mL of CH₃OH) in a Pyrex cell with a side window. The 0.5–1.5 wt % of Pt cocatalyst was photodeposited on the NaNbO₃ catalyst by adding a calculated amount of H₂PtCl₆ solution into the reaction solution. The light source was a 300 W Xe arc lamp without a filter ($\lambda > 300$ nm). The H₂ evolution was measured with an online gas chromatograph (GC-8A, Shimadzu) with a thermal conductivity detector (TCD) according to the standard curve. After the H₂ evolution persisted for 8 h, the resulting NaNbO₃ powder was separated by centrifugation and washed with the distilled water for several times. The sample was then dried in vacuum at 250 °C and continually heated at 400 °C for 3 h to remove organic compounds adsorbed on the surface of the catalyst. The obtained sample with Pt loaded was further tested for the photoactivity of CO₂ reduction.

CO₂ Photoreduction. The CO₂ photoreduction experiments were carried out in a gas closed circulation system with an upside window. The Pt-loaded catalyst powder (0.1 g) was dispersed on a small glass cell and then located in a Pyrex reaction cell. After that, 3 mL of distilled water was added into the gas closed reaction system. The whole system was then evacuated and filled with 80 kPa of pure CO₂ gas. The light source was a 300 W Xe arc lamp without a filter. The organic products were sampled and measured with a gas chromatograph (GC-14B, Shimadzu) equipped with a flame ionization detector (FID) according to the standard curves. The H₂ evolution was measured with an online gas chromatograph (GC-8A, Shimadzu) with a TCD detector according to the standard curve.

Theoretical Calculation. The band structures, densities of state (DOS), and partial densities of state (PDOS) of cubic and orthorhombic NaNbO₃ were calculated using the plane-wave density functional theory (DFT) with the CASTEP program package.³⁸ The core electrons were replaced by ultrasoft pseudopotentials with a plane-wave basis cutoff energy of 370 eV, and the interactions of exchange and correlation were treated within the framework of the local density approximation (LDA). The FFT grids of basis in all the models were 24 × 24 × 24 and 32 × 90 × 30 for *c*-NaNbO₃ and *o*-NaNbO₃, respectively. The *k*-point sets of 6 × 6 × 6 for *c*-NaNbO₃ and 5 × 2 × 5 for *o*-NaNbO₃ were used.

RESULTS AND DISCUSSION

Crystal Structure. The basic perovskite NaNbO₃, which has a cubic structure with the space group of *Pm* $\bar{3}$ *m* (Figure 1),

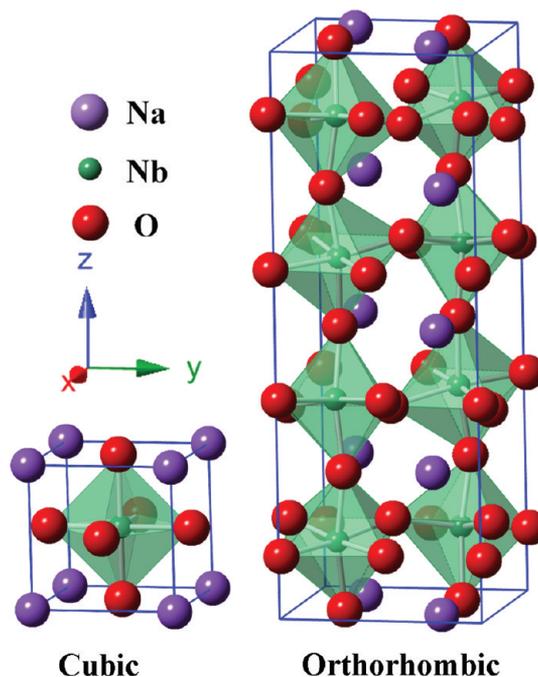

Figure 1. Schematic crystal structures of cubic and orthorhombic NaNbO₃.

is only stable at high temperature (>913 K).^{31,36} When cooling down from high temperature, NaNbO₃ undergoes a series of phase transitions from cubic to rhombohedral via intermediate tetragonal and orthorhombic phases. At room temperature, the common phase of NaNbO₃ is an antiferroelectric orthorhombic

phase, space group of $Pbcm$, $a = 5.506 \text{ \AA}$, $b = 5.566 \text{ \AA}$, and $c = 15.52 \text{ \AA}$ (Figure 1).³⁹ This phase processes an “octahedral tilting” with three independent tilts as a $\sqrt{2}a_0 \times \sqrt{2}a_0 \times 4a_0$ supercell of the basic cubic perovskite cell, where a_0 is the cubic lattice parameter, 3.906 \AA .⁴⁰

The crystallographic phases of as-prepared NaNbO_3 were determined by X-ray diffraction (XRD) (Figure 2). The patterns

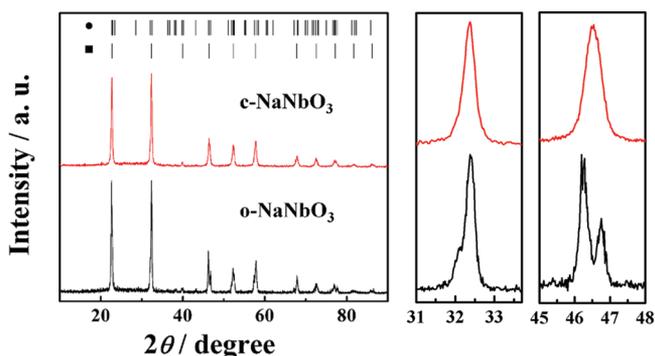

Figure 2. XRD patterns of the as-prepared NaNbO_3 samples (●, orthorhombic; ■, cubic).

show that the NaNbO_3 prepared through the FAPO route crystallized in a cubic system with the space group of $Pm\bar{3}m$,

whereas the NaNbO_3 synthesized by a PC method was formed in an orthorhombic system with the space group of $Pbcm$. The diffraction peaks, of which 2θ are about 32.5° and 46.5° , show the obvious difference between cubic and orthorhombic NaNbO_3 . All peaks in these patterns could be indexed to the JCPDS database card (JCPDS-075-2102 for cubic and JCPDS-073-0803 for orthorhombic). Because the surface energy of $c\text{-NaNbO}_3$ is higher than that of $o\text{-NaNbO}_3$, by common synthetic methods, the orthorhombic phase favors to form at room temperature.^{32,41} The formation of $c\text{-NaNbO}_3$ by a FAPO method is probably attributed to the addition of the surfactant P-123, which stabilized the surface of the $c\text{-NaNbO}_3$ crystal in solution. The study of the detailed mechanism of crystal growth is under way. The average crystallite sizes of $c\text{-NaNbO}_3$ and $o\text{-NaNbO}_3$ were calculated to be 18.5 and 23.1 nm using the Debye–Scherrer equation. The lattice parameters of NaNbO_3 were refined by the least-squares method (as listed in Table 1).

Transmission electron microscopy (TEM) and high-resolution transmission electron microscopy (HR-TEM) were further used to confirm the crystal structures of the as-prepared samples (Figure 3). The $c\text{-NaNbO}_3$ sample is constituted by particles with a uniform cuboid morphology. The cuboids are generally 40 nm in length. The $o\text{-NaNbO}_3$ sample contains irregular and cuboid particles. As exhibited in Figure 3b, the $c\text{-NaNbO}_3$ sample exhibits two mutually perpendicular fringes with the same d -spacing, 3.91 \AA , which could be indexed to the

materials	crystal systems	lattice parameters (Å)	band gaps (eV)	surface areas ($\text{m}^2\cdot\text{g}^{-1}$)	H_2 evolution ($\mu\text{mol}\cdot\text{h}^{-1}$)	CH_4 evolution ($\mu\text{mol}\cdot\text{h}^{-1}$)
$c\text{-NaNbO}_3$	cubic	$a = 3.909(2)$	3.29	28.6	127	0.486
$o\text{-NaNbO}_3$	orthorhombic	$a = 5.577(3), b = 5.524(3), c = 15.579(7)$	3.45	26.4	72.3	0.245

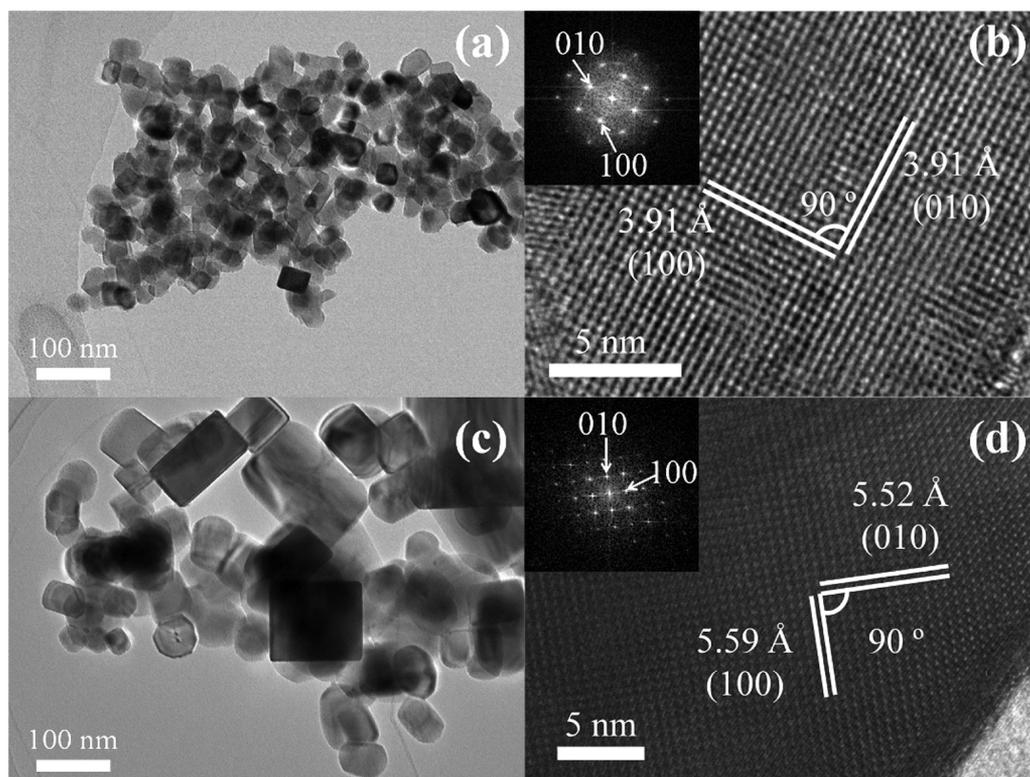

Figure 3. TEM (a) and HR-TEM (b) images of $c\text{-NaNbO}_3$, TEM (c) and HR-TEM (d) images of $o\text{-NaNbO}_3$. The insets are the corresponding FFT patterns of two samples.

{010} and {100} plane of *c*-NaNbO₃. From Figure 3d, two sets of orthorhombic fringes with lattice spacings of 5.52 and 5.59 Å are observed, corresponding to the {010} and {100} planes of *o*-NaNbO₃, respectively. The insets of Figure 3b,d give the corresponding fast Fourier transform (FFT) patterns of two samples, which show the clear evidence to distinguish the two phases. The BET surface areas were measured to be 28.6 and 26.4 m²·g⁻¹ for *c*-NaNbO₃ and *o*-NaNbO₃, respectively.

Photophysical Property. UV–visible absorption spectra of *c*-NaNbO₃ and *o*-NaNbO₃ powder samples are shown in Figure 4. Both the two samples have the only intense absorption

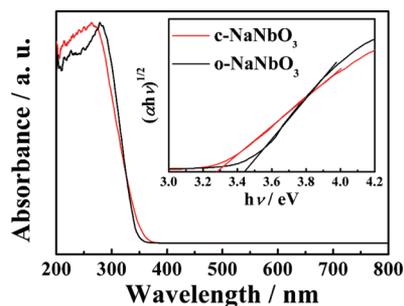

Figure 4. UV–vis absorption spectra of the as-prepared NaNbO₃ samples. The inset is the corresponding $(\alpha h\nu)^{1/2}-h\nu$ curves.

with steep edges in the UV region. Compared with the absorption edge of *o*-NaNbO₃, that of *c*-NaNbO₃ has a slight red shift, suggesting that the *c*-NaNbO₃ could absorb longer wavelength light. The band gaps (E_g) of *c*-NaNbO₃ and *o*-NaNbO₃ were determined according to the following equation

$$(\alpha h\nu)^n = A(h\nu - E_g)$$

in which α , ν , A , and E_g are the absorption coefficient, light frequency, proportionality constant, and band gap, respectively.⁴² The value of index n depends on the property of materials, where $n = 2$ for the direct-band-gap semiconductor and $n = 1/2$ for the indirect-band-gap semiconductor.⁴² For both NaNbO₃ samples, the indexes n were determined to be 1/2 according to the relationship between $\log(\alpha h\nu)$ and $\log(h\nu - E_g)$. From the inset of Figure 4, the values of the band gaps for *c*-NaNbO₃ and *o*-NaNbO₃ are determined to be 3.29 and 3.45 eV, respectively. The *c*-NaNbO₃ sample possesses a narrower band gap than *o*-NaNbO₃.

H₂ Evolution Activity. The H₂ evolutions from CH₃OH aqueous solution (50 mL of CH₃OH + 220 mL of H₂O) over 0.5 wt % of Pt-loaded powder catalysts (0.3 g) under the irradiation of a Xe lamp ($\lambda > 300$ nm) are presented in Figure 5a. As mentioned previously, both the cubic and the orthorhombic NaNbO₃ are constructed of a basic perovskite structure. However, their photocatalytic activities are significantly different: *c*-NaNbO₃ > *o*-NaNbO₃. The H₂ evolution amounts increased almost linearly in 8 h and were about 127 and 72.3 $\mu\text{mol}\cdot\text{h}^{-1}$ for *c*-NaNbO₃ and *o*-NaNbO₃, respectively. The difference in the photocatalytic activity between *c*-NaNbO₃ and *o*-NaNbO₃ is probably attributed to their different electronic structures and will be discussed in the following section.

For H₂ evolution, the Pt serves as a cocatalyst to supply the reactive site where H₂ could generate easily due to the low H₂ overpotential on the Pt surface. The loaded Pt cocatalysts largely affect the H₂ generation efficiency. The photocatalytic performance is influenced by the cover ratio and size of the

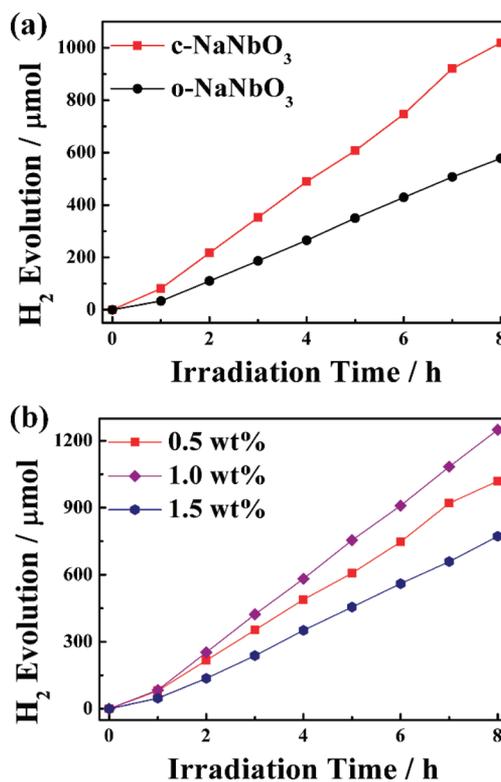

Figure 5. (a) Photocatalytic H₂ evolution from the aqueous methanol solution over *c*-NaNbO₃ and *o*-NaNbO₃ samples with a loading of 0.5 wt % Pt. (b) Photocatalytic H₂ evolution from the aqueous methanol solution over *c*-NaNbO₃ samples with 0.5, 1.0, and 1.5 wt % Pt loaded.

cocatalyst that could be adjusted by the loading amount.⁴³ Since the *c*-NaNbO₃ sample possessed a special morphology with a relatively high surface area, the optimization of the Pt cocatalyst was performed carefully in this study. The 0.5, 1.0, and 1.5 wt % of Pt cocatalyst were deposited on the *c*-NaNbO₃ surface, and their corresponding photocatalytic H₂ evolutions are plotted in Figure 5b. The H₂ evolution rates over *c*-NaNbO₃ were 127.4, 156.1, and 97.3 $\mu\text{mol}\cdot\text{h}^{-1}$ for 0.5, 1.0, and 1.5 wt % of Pt loading, respectively. The 1.0 wt % of loading amount supplied a proper cover ratio and size of cocatalyst and hence induced the highest H₂ evolution rate for the *c*-NaNbO₃ photocatalyst.

CO₂ Photoreduction Activity. The photoreductive ability of NaNbO₃ could also be applicable for converting CO₂ into useful organic fuels, such as CH₄. Figure 6a exhibits CH₄ generation from CO₂ photoreduction over *c*-NaNbO₃ and *o*-NaNbO₃ with a loading of 0.5 wt % Pt. The CH₄ evolution rates over *c*-NaNbO₃ and *o*-NaNbO₃ were determined to be 0.486 and 0.245 $\mu\text{mol}\cdot\text{h}^{-1}$, respectively. The photoactivity order is the same as that of the H₂ evolution reaction, *c*-NaNbO₃ > *o*-NaNbO₃. The optimization of the loading amount of Pt cocatalyst was also carried out for CO₂ photoreduction. The 1.0 wt % of Pt-loaded *c*-NaNbO₃ photocatalyst showed the best photocatalytic activity, which is in good agreement with the H₂ evolution result (Figure 6b). These results reveal that the processes of electron excitation and transfer are similar in these two kinds of reactions.

It is well known that the CO₂ photoreduction mainly undergoes two courses, including oxidation and reduction processes. In the oxidation process, H₂O is oxidized to O₂ ($2\text{H}_2\text{O} + 4\text{h}^+ \rightarrow \text{O}_2 + 4\text{H}^+$). In the reduction course, there is a chain reaction to

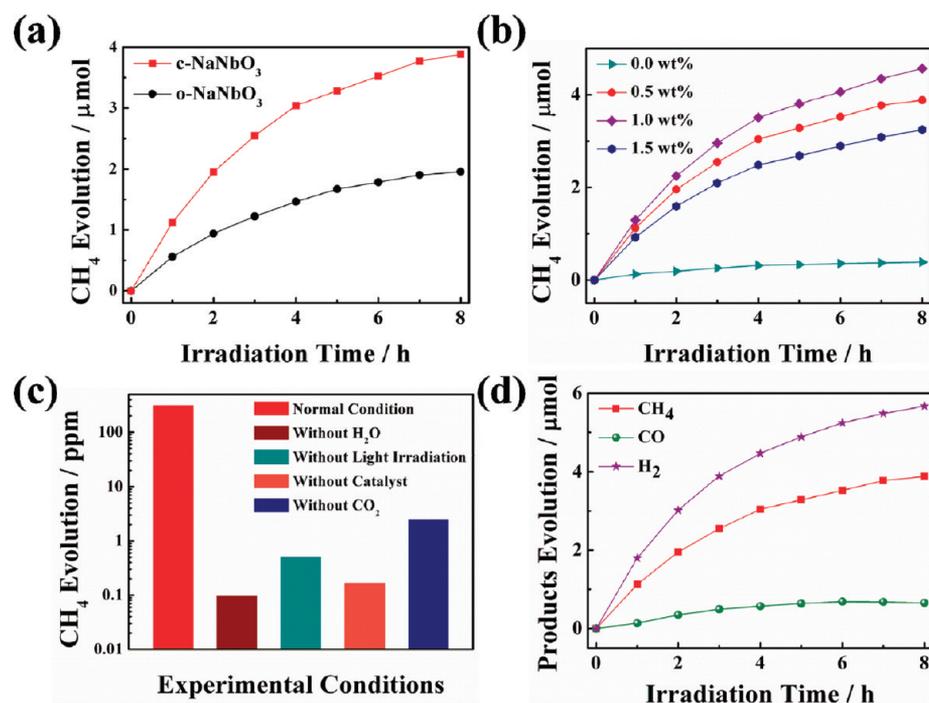

Figure 6. (a) CH₄ evolution in gas-phase reaction over c-NaNbO₃ and o-NaNbO₃ samples (with loading 0.5 wt % Pt). (b) CH₄ evolution over c-NaNbO₃ samples with 0.0, 0.5, 1.0, and 1.5 wt % Pt loaded. (c) CH₄ evolution in reference experiments in the condition without H₂O, CO₂, light irradiation, and catalyst compared with that in normal conditions. (d) CH₄, CO, and H₂ evolution in gas-phase reaction over 0.5 wt % Pt loaded c-NaNbO₃ sample.

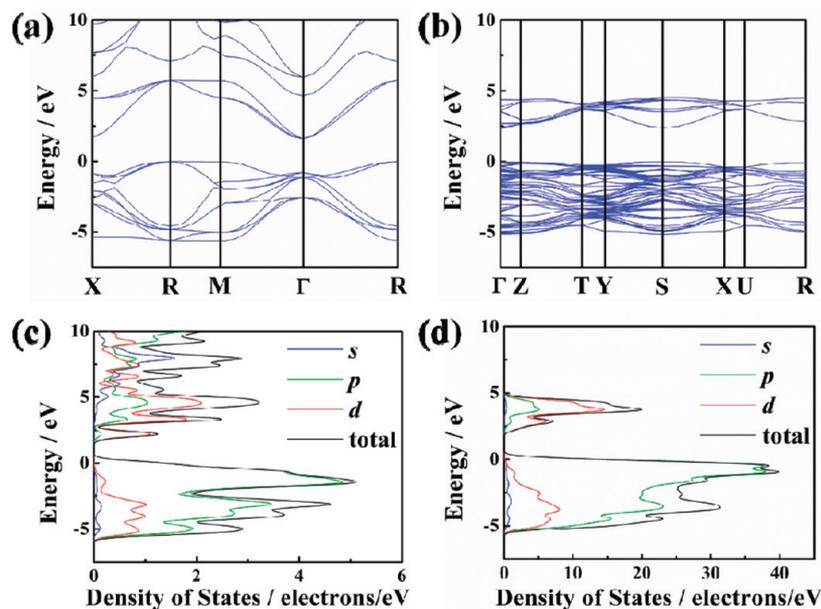

Figure 7. Calculated band structures of c-NaNbO₃ (a) and o-NaNbO₃ (b). The DOS of c-NaNbO₃ (c) and o-NaNbO₃ (d).

reduce CO₂ to CH₄ (CO₂ + 2H⁺ + 2e⁻ → HCOOH, HCOOH + 2H⁺ + 2e⁻ → HCHO + H₂O, HCHO + 2H⁺ + 2e⁻ → CH₃OH, CH₃OH + 2H⁺ + 2e⁻ → CH₄ + H₂O).⁴⁴ To confirm that the CH₄ was generated from the photoreduction reaction, reference experiments were carried out over c-NaNbO₃. Figure 6c shows the concentration of CH₄ evolution when the reference experiments were carried out for 8 h. When the experiment was carried out in the absence of H₂O, only 0.1 ppm of CH₄ was detected. In the absence of catalyst or light irradiation, there were merely 0.33 and 0.15 ppm of CH₄,

respectively. Since there is about 1 ppm of CH₄ in the natural air, the CH₄ in the above-mentioned experiments is considered as the contamination from air during samplings. Nevertheless, in the case that the CO₂ gas was replaced by Ar gas, 1.2 ppm of CH₄ was found. This value is obviously higher than that in natural air. As the sample was prepared from a carbon-containing precursor and NaNbO₃ possesses an alkaline surface, it is difficult to remove all the CO₂ from the sample surface even after a long calcination time. We once tested the CO₂ amount in the reaction system during the reference experiment without CO₂

and found that about 300 ppm of CO₂ evolved from the sample surface. Therefore, a small amount of CH₄ should be generated from the photoreduction of the remaining CO₂ on the sample surface. Consequently, all the above-mentioned reference experiments prove that the H₂O supplies protons, CO₂ offers a carbon source, and the photocatalyst gives the redox potentials for the whole reaction to finally produce CH₄.

Besides CH₄, other hydrocarbon compounds (C₂H₄, C₂H₆, and C₃H₈) were also generated in the reaction. However, the productions of these organic compounds were much lower than that of CH₄. This results suggest that the long chain organic molecules are generated via photocatalytic reforming of CH₄, and CH₄ is the source of this reaction.^{45,46} Inorganic by-products CO and H₂ were also detected, as shown in Figure 6d. CO is a common byproduct in the CO₂ reduction. Along with the CO₂ reduction over c-NaNbO₃, CO was produced with the rate of 0.082 μmol·h⁻¹. Although the reduction potential of H₂O to H₂ (-0.41 V vs NHE, pH = 7) is more negative than that of CO₂ to CH₄ (-0.24 V vs NHE, pH = 7),⁴⁴ the evolution rate of H₂ (0.71 μmol·h⁻¹) was higher than that of CH₄ (0.486 μmol·h⁻¹ catalyst). This could be attributed to that more electrons are consumed in CO₂ reduction (CO₂ + 6H₂O + 8e⁻ → CH₄ + 8OH⁻) than those in H₂O reduction

(2H₂O + 2e⁻ → H₂ + 2OH⁻). Thus, the H₂ is easier to be generated dynamically.

Electronic Structure. The crystal structures of c-NaNbO₃ and o-NaNbO₃ are constructed of the same basic perovskite unit. Moreover, the band gap difference between the two materials is less than 0.2 eV. However, the photocatalytic H₂ generation and CO₂ reduction activities of c-NaNbO₃ are severely higher than those of o-NaNbO₃. Thus, the detailed investigation on band structure was carried out to understand this experimental phenomenon. The DFT calculation was used to investigate the electronic structures of c-NaNbO₃ and o-NaNbO₃. Figure 7a,b shows the calculated band structures of c-NaNbO₃ and o-NaNbO₃, respectively. The band structures indicate that both of them are typical indirect-band-gap semiconductors, which is consistent with the analysis of UV-visible absorption spectra. The theoretical band gaps of c-NaNbO₃ and o-NaNbO₃ are 1.63 and 2.33 eV, respectively, which are smaller than the values from experimental data. This difference is caused by the limitation of the LDA functional that underestimates the band gaps in semiconductor simulation. Besides the narrower band gap, the conduction bands of c-NaNbO₃ are more dispersive than those of o-NaNbO₃, which indicates that the photogenerated electrons in c-NaNbO₃ possess a smaller effective mass and, therefore, higher migration ability, inducing that c-NaNbO₃ shows higher photoreduction activity than o-NaNbO₃. Further information is obtained from the DOS and PDOS of c-NaNbO₃ and o-NaNbO₃ (Figure 7c,d). Both of the valence band tops of c-NaNbO₃ and o-NaNbO₃ are constructed from O 2p orbitals, and thus, they locate at similar energy levels, which is consistent with the XPS data shown in Figure S1a (Supporting Information). Nevertheless, the conduction band bottoms of c-NaNbO₃ and o-NaNbO₃ are significantly different. The energy level of the conduction band bottom in c-NaNbO₃ is lower than that in o-NaNbO₃. This difference is attributed to the variant octahedral ligand field of o-NaNbO₃ that changes Nb–O bond lengths and O–Nb–O

Table 2. Optimized Bond Lengths and Bond Angles of NaNbO₃

	Nb–O bond length (Å)	O–Nb–O bond angle (degree)
c-NaNbO ₃	1.966	90.00
o-NaNbO ₃	1.971 (a–o)	86.13 (a–o–c) 93.65 (a–o–d)
	1.974 (b–o)	85.84 (a–o–e) 93.28 (a–o–f)
	2.084 (c–o)	86.73 (b–o–c) 93.47 (b–o–d)
	1.895 (d–o)	86.33 (b–o–e) 93.14 (b–o–f)
	2.075 (e–o)	89.27 (c–o–d) 84.82 (c–o–e)
	1.892 (f–o)	96.20 (f–o–d) 89.71 (f–o–e)

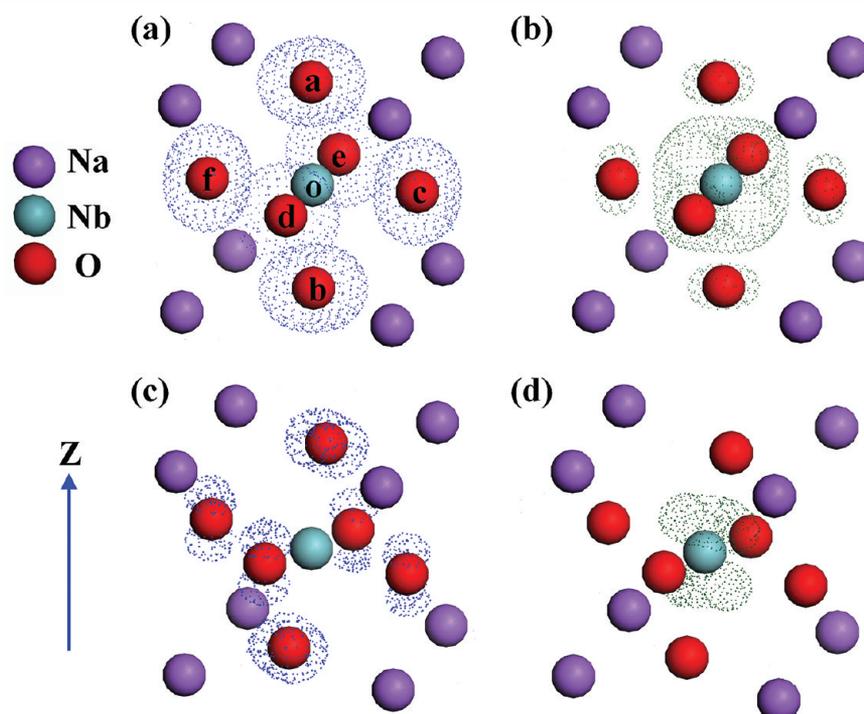

Figure 8. Frontier orbital distributions of NaNbO₃: HOMO (a) and LUMO (b) of c-NaNbO₃; HOMO (c) and LUMO (d) of o-NaNbO₃.

bond angles (as listed in Table 2) of the basic cubic crystal structure. When the crystal structure of NaNbO_3 changes from cubic to orthorhombic style, the tilts of Nb–O bonds and the shifts of bond lengths contribute to lowering the energy; however, the Nb–O bond lengths in the z direction are nearly the same. Moreover, the frontier orbital distributions also supply the explanation for the photocatalytic activity difference (Figure 8). As the conduction band bottom of $c\text{-NaNbO}_3$ possesses a delocalized orbital covering Nb and O atoms, the photogenerated electrons could transfer along the x , y , and z directions isotropically. Nevertheless, for $o\text{-NaNbO}_3$ that possesses a localized conduction band bottom, the frontier orbital distributions exhibit a nonisotropy figure, inducing that the photogenerated electrons favor the migration along the z direction other than the x and y directions. Therefore, the high symmetry in the crystal structure of $c\text{-NaNbO}_3$ is beneficial for the transfer of photogenerated electrons and, subsequently, the better photoreduction activity.

CONCLUSIONS

In conclusion, cubic and orthorhombic NaNbO_3 were synthesized to study the effect of crystallographic symmetry on the electronic structure and photocatalytic activity in the perovskite structure in detail. This $c\text{-NaNbO}_3$ shows a narrower band gap (3.29 eV) than the common $o\text{-NaNbO}_3$ (3.45 eV). In photocatalytic H_2 generation, $c\text{-NaNbO}_3$ ($127 \mu\text{mol}\cdot\text{h}^{-1}$) shows higher activity than $o\text{-NaNbO}_3$ ($72.3 \mu\text{mol}\cdot\text{h}^{-1}$). For CO_2 photoreduction in the gas phase, the CH_4 evolution rate over $c\text{-NaNbO}_3$ ($0.486 \mu\text{mol}\cdot\text{h}^{-1}$) is about twice that over $o\text{-NaNbO}_3$ ($0.245 \mu\text{mol}\cdot\text{h}^{-1}$). Theoretical calculation demonstrated that the band gap difference between the two phases of NaNbO_3 is caused by the variant octahedral ligand field. Furthermore, the high symmetry in $c\text{-NaNbO}_3$ results in its unique electronic structure that is beneficial for the electron excitation and transfer and thus contributes to its higher photocatalytic activity compared with $o\text{-NaNbO}_3$. The present study evidences that reforming the crystal structure of the perovskite semiconductor toward a higher symmetry can improve the photoelectron excitation and transfer. Therefore, it offers a new idea to enhance the photocatalytic efficiency in other perovskite or multilayered perovskite photocatalysts.
