The Stability of Photoelectrodes

J. O'M. Bockris and K. Uosaki

doi: 10.1149/1.2133256
of electrode surface that tended to behave differently (with and without gas evolution and with and without concentration gradients) were smaller tending to have linear dimensions less than 1 mm.

The electrodes from the automotive battery showed a distinct change in impressed voltage required to charge at a constant current density of 10.00 mA cm⁻² at −22°C as the temperature was raised or lowered. Figure 3 shows that the slope of the cooling run (dV/dT) is greater than the warming run, but each shows an abrupt change of about 10 mV at −22°C. Valeriote (4) has suggested this is freezing of the liquid in the pores of the heterogeneous PbSO₄-PbO₂ layer at the anode.

Acknowledgments
This work was supported by the Defence Research Board of Canada. Most of the experimental work was performed by R. J. Raine.

Manuscript received Aug. 24, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the University of Victoria.

The Stability of Photoelectrodes

J. O'M. Bockris* and K. Uosaki

School of Physical Sciences, The Flinders University of South Australia, Adelaide, Australia

The stability of a semiconductor electrode under illumination is one of the key points in the prospect for the photoelectrochemical production of hydrogen.

Recently, Harris et al. (1) reported that TiO₂ single crystals were not stable and the photocurrents decreased with time in all cases they examined. Similar results were reported by Wrighton et al., although they found no sign of decomposition of TiO₂ (2). Also, Yoneyama et al. (3) found that p-GaP was not stable under illumination, although they mentioned that there could be a possibility of obtaining a stable condition by choosing a suitable electrolyte, etc.

The stability of a TiO₂ single crystal cut perpendicu-
lar to the c axis (1001) face obtained from Nakazumi Crystal Corporation and of a p-type GaP wafer [Zn doped, (111) face] donated by Dr. K. Akita of the Fujitsu Laboratory Limited was examined in 1N NaOH solution.

The TiO₂ single crystal was reduced in a hydrogen atmosphere at 800°C for 5 hr (4). An ohmic contact to TiO₂ was obtained by means of indium (5) and a copper wire was soldered onto the indium. The specific resistance of the crystal was 2.0 Ω·cm.

A p-type GaP was etched in HNO₃-HCl (2:1 mixture) (6) and an ohmic contact was made by means of Zn-In alloy (3). The specific resistance was 1.8 Ω·cm.

The semiconductor electrodes were mounted in a Teflon electrode holder with an epoxy resin so that only the faces to be examined were exposed to the solution. The electrode area was 0.125 cm². A 900W Xe lamp (Canrad-Hanovia 538 C1) was used as a light source and an infrared absorbing filter (Oriel G-776-1100) was placed between the light source and the electrochemical cell. A PAR 173 potentiostat was employed to maintain the electrodes at given potential.

The results are shown in Fig. 1 for TiO₂ and in Fig. 2 for p-GaP.

Although Harris et al. (1) mentioned that the photocurrent of TiO₂ decreased in all cases studied by them and Wrighton et al. (2) reported the fall of the photocurrents with time but without details, the photocurrents in our work did not change detectably over 1000 min (Fig. 1).

Also, the photocurrent of p-GaP decreased only slightly with time (Fig. 2). This behavior is different from that reported by Yoneyama et al. (3).

These results suggest that the stability of the photocurrent at semiconductors depends upon the preparation, dopant, and pretreatment of the semiconductor.
and also solution and illumination conditions. Thus, for the TiO$_2$ electrode, we carried out a hydrogen atmosphere reduction for 5 hr at 800°C, whereas Harris et al. (1) used 15 min at 600°C and Wrighton et al. (2) reduced TiO$_2$ at 700°C for 4 hr.

The main difference both for the TiO$_2$ and the GaP crystals seems to be the illumination condition. The intensity of light was 0.08 W/cm$^2$ in this work, 1.4 W/cm$^2$ in the experiment of Harris et al. (1), and $8 \times 10^{-6}$ einstein/min (1 mm diam spot) (351, 361 nm doublet emission) which is equivalent to about 5 W/cm$^2$ in the work of Wrighton et al. (2). Accordingly, the current density of this work was 1.7 mA/cm$^2$ and that of Harris et al. and Wrighton et al. were 16 mA/cm$^2$ at maximum and 100 mA/cm$^2$, respectively.

The intensity of light was not reported by Yoneyama et al. (3) but one may hypothesize that it is stronger than that of this work, because the light of a 500W Hg lamp was focused on to the electrode, while collimated light of a 900W Xe lamp was used in this work.

Manuscript submitted Aug. 17, 1976; revised manuscript received Sept. 20, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 Journal. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.
