Abstract

Catalytic upgrading of pyroligneous acid, by-product from slow pyrolysis of woody biomass for char production, was carried out using zirconia-supported iron-oxide catalysts under a steam atmosphere at temperatures ranging from 623 to 723 K, and the effect of ZrO\textsubscript{2} content in the ZrO\textsubscript{2}–FeO\textsubscript{X} catalysts on catalytic activity and ketone yields was investigated. It was demonstrated that hydroxyacetone and carboxylic acids (acetic and propionic acids) in the pyroligneous acid were converted into aliphatic ketones (acetone and 2-butanone) via a ketonization reaction over the ZrO\textsubscript{2}–FeO\textsubscript{X} catalyst. However, reaction inhibition by metal impurities in the pyroligneous acid such as potassium (K) and magnesium (Mg) was also observed. These metal impurities could be removed from the pyroligneous acid without changing the organic composition by using an ion-exchange resin. The removal of the metal impurities was effective in increasing the ketone yields. Moreover, as the W/F value (W: amount of catalyst, and F: flow rate of the pyroligneous acid in the feed) increased, the ketone yield increased up to approximately 30 C mol\%, and the ketone fraction in the liquid product reached 55 C mol\%.

Keywords: Ketones; Pyroligneous acid; Woody biomass; Iron-oxide catalyst
1. Introduction

In response to the need for alternatives to petroleum-based energy and the desire to use renewable resources for chemical production, many efforts have recently been concentrated on conversion of biomass into energy and useful chemicals. Sustainability in energy recovery from biomass such as steam gasification of char is becoming attractive because biomass to energy conversion adds no additional greenhouse gases to the atmosphere [1, 2]. The char as high-quality solid fuel is produced from pyrolysis and its higher yield can be recovered by slow pyrolysis than fast or flash ones [3, 4]. During slow pyrolysis (low-moderate temperature and slow heating rate process), volatile matters are condensed into two liquid fractions, an aqueous and an organic liquid fractions. The organic liquid fraction has higher carbon concentration and heating value than the aqueous one because the aqueous fraction is characterized by high water content, relative low carbon concentration, and very low heating value [5]. Therefore, the organic liquid fraction has potentiality for fuel application [6]. The aqueous fraction, also known as pyroligneous acid, will create waste-water disposal problems, although this could be incinerated [3,5].

The pyroligneous acid, a by-product from slow pyrolysis of woody biomass for char production, dissolves organics (such as acetic acid, methanol, phenolic compounds) in water. Therefore, the possible wet utilization basis and catalytic upgrading is required for its conversion to higher value chemicals. In the previous study, we have developed ZrO$_2$–FeO$_X$ catalysts to selectively produce valuable chemicals such as phenol and ketones from palm waste, sewage sludge, and coliform-fermented residue-derived tars [7–9]. Because the ZrO$_2$–FeO$_X$ catalyst possesses oxidation activity towards hydrocarbons, it is possible to reduce the amount of deposited carbonaceous residue on the catalyst [10].

In aqueous solution of pyroligneous acid, many organics such as carboxylic acid and alcohol were contained. Because the ZrO$_2$–FeO$_X$ catalysts possess ketonization activities from carboxylic acid and alcohol, we examined the catalytic upgrading of the pyroligneous acid derived from woody biomass over ZrO$_2$–FeO$_X$ catalysts to produce useful chemicals. Here, the catalytic upgrading is the process integration of slow pyrolysis for biomass utilization. The effects of the reaction temperature, catalyst composition, metal impurities in the pyroligneous acid, and $W/F$ values on the catalytic activity and product yields were investigated. Moreover, catalytic reactions using model compounds were also carried out in order to clarify the reaction routes.

2. Experimental

2.1. Material

The pyroligneous acid was produced from slow pyrolysis of dried Japanese cedar woodchips for char production using a horizontal screw-conveyor reactor. The chips have an average size of $10 \times 10 \times 2$ mm, 50.9 wt.% carbon and 3
The pyrolysis was carried out with a feeding rate, an average residence time, a heating rate, a peak temperature, and a gas pressure inside the reactor of $270 \, \text{g h}^{-1}$, 47 s, 5.0–5.5 $\degree\text{C s}^{-1}$, 500 $\degree\text{C}$, and 1.0 atm, respectively [2]. The slow pyrolysis produces char, heavy tar, light tar which consist of two separate phases: organic liquid (water-insoluble fraction) and pyroligneous acid (water-soluble fraction), and gaseous products. Carbon concentration of feed for the pyrolysis (woodchips) and the products (char, heavy tar, organic liquid, pyroligneous acid) was analyzed by elemental analysis (Costech, ECS 4010 CHNS-O) and the weights of used feed and the products were measured and then, each of them was calculated in C mol. During the pyrolysis, gas and non-condensable volatile (gaseous products) were collected in gas pack and then analyzed by gas chromatography with TCD and FID detectors. Total gas produced was also calculated in C mol. All the products after the pyrolysis were divided by C mol used feed to determine the yield in C mol%.

Furthermore, the chemical compositions of pyroligneous acid (feed for the catalytic reaction) were analyzed using a GC-17A (Shimadzu, CP-Pora PLOT Q capillary column) for identification of volatile chemical compounds such as acetaldehyde, methanol, acetone, and 2-butanone using ethanol as an internal standard. Then, higher vapor pressure chemicals such as hydroxyacetone, acetic acid, phenol were analyzed by a GC-2014 (Shimadzu, DB-WX capillary column), and a GC/MS-QP5050 (Shimadzu, CP-Pora PLOT Q_DB-WX capillary columns) with n-butanol as an internal standard. Because heavy components undetectable by gas chromatography were contained in the pyroligneous acid, the amount of carbon measured by elemental analysis was considered to be the total amount of carbon in the pyroligneous acid. The yield of pyroligneous acid was shown as C mol% by divided C mol pyroligneous acid based on GC analysis with its C mol based on elemental analysis. Moreover, the GC/MS analysis was used for the quantitative identification of chemical compounds in the pyroligneous acid. Then, the amount of metal impurities in the pyroligneous acid was determined by X-ray fluorescence (XRF, Rigaku Corporation, Supermini-GR16008).

2.2. Catalyst preparation and characterization

All reagents were purchased from Wako Pure Chemical Industries, Ltd (Japan). The zirconia-supported iron-oxide ($\text{ZrO}_2(\text{Y})\text{-FeO}_x$: $Y = \text{wt.}\% \text{ZrO}_2$) catalysts were prepared using a co-precipitation method in an aqueous solution of $\text{Fe(NO}_3)_3\cdot9\text{H}_2\text{O}$ and $\text{ZrO(NO}_3)_2\cdot2\text{H}_2\text{O}$ using aqueous ammonia. The obtained catalysts were calcined at 773 K for 2 h in an air atmosphere [9]. Catalysts with $\text{ZrO}_2$ content of 8.9, 50, and 70 wt.% were prepared, and their crystallinity characterized by X-ray diffraction (XRD, JEOL, JDX-8020).

2.3. Cation-exchange treatment for the pyroligneous acid

-3-
XRF analysis revealed that the pyroligneous acid contained potassium (K) and magnesium (Mg) as metal impurities. A cation-exchange resin [MP Biomedicals, LLC: Amberlite®IR-120 plus (H)] was used to remove alkali and alkaline earth metals such as K and Mg from the pyroligneous acid. The treatment was carried out in standard glass bottle (25 ml) by placing 5 ml of pyroligneous acid into 2 g of the resin for 24 h at 275 K with occasional shaking.

2.4. Catalytic reaction

Catalytic reactions were carried out in a fixed bed flow reactor for 2 h at 623–723 K under atmospheric pressure. Figure 1 shows a schematic of the experimental apparatus. ZrO$_2$–FeO$_x$ catalysts were pelletized without any binders, then crushed and sieved to provide pieces 300–850 µm in diameter. The pyroligneous acids prior to and after cation-exchange treatment were used as feedstocks. Nitrogen gas (10 cm$^3$ min$^{-1}$) was introduced as the carrier gas. The pyroligneous acids and H$_2$O were mixed in a 1:1 weight ratio and fed into the reactor at 2 ml h$^{-1}$ using a syringe pump. The time-factors, $W/F$, were 1–4 h. The liquid and gaseous products were collected in an ice/water trap and gas pack, respectively. The liquid product and catalyst crystallinity after each reaction were analyzed using the same gas chromatographs, elemental analyzer, and XRD as mentioned above. Gaseous products were analyzed by gas chromatography [GS-20B (Shimadzu, FID detector) and GC-8A (Shimadzu, TCD detector)].

3. Results and Discussion

3.1. Chemical composition of the pyroligneous acid

During pyrolysis of the woodchips biomass, organic chemical bonds such as C-C and C-O bonds were decomposed by dehydration, hydrolysis, oxidation, decarboxylation, and depolymerization to produce gaseous products, water vapor, tar, and volatiles. The water vapor, tar, and volatiles generated from the biomass were condensed and collected by filter and cold traps of different temperatures (393, 278, and 233 K, respectively), and three types of tar (heavy tar, an organic liquid fraction and pyroligneous acid) were obtained. Incondensable volatiles and gaseous products were recovered as gas products. The remaining residue of the pyrolysis process was recovered as char. Yields of the pyroligneous acid, the organic liquid and heavy tar on the basis of carbon concentration in the woodchips were 14.0, 3.3, and 39.8 C mol%, respectively, and the yields of all of pyrolysis products including gas and char are listed in Table 1.

Since the chemicals contained in the pyroligneous acid dissolved in water, it was considered that they consisted of polar compounds of low molecular weight, and thus the pyroligneous acid was mainly derived from the pyrolysis of
cellulose and hemicellulose. On the other hand, the portion of the organic liquid that was insoluble in water was considered to be derived from lignin [11]. In this study, the pyroligneous acid, which was an organic-containing water solution, was selected as the feedstock for the catalytic reaction, and the amount of carbon in the water measured by elemental analysis was approximately 20.7 wt.%. Based on data from GC and GCMS analyses, the chemical compounds in the pyroligneous acid were grouped into hydroxyacetone, aliphatic ketones (acetone, 2-butane, and 3-pentane), carboxylic acids (acetic and propionic acids), cyclic ethers and ketones, aldehydes, methanol, phenols, light components (detectable by GC), and heavy components (undetectable by GC). Yields of hydroxyacetone, aliphatic ketones, and carboxylic acids on the basis of carbon concentration in the pyroligneous acid were 7.0, 4.3, and 8.6 C mol%, respectively, and detailed yields of all of chemical composition are shown in Table 2.

3.2. Effect of reaction temperature on product yields and catalyst stability

To understand the effect of temperature during the catalytic reaction of the pyroligneous acid, reactions were carried out at 623, 673, and 723 K. Product yields after reaction using a ZrO$_2$(8.9)–FeO$_X$ catalyst are shown in Fig. 2. Product yields without catalyst are also shown in this figure for comparison. Because many chemicals undetectable by the gas chromatographs were contained in the pyroligneous acid, the amount of carbon measured by the elemental analyzer was assumed to be the total amount of carbon in the pyroligneous acid. The product yield without catalyst was almost the same as the composition of the feedstock. In contrast, in the reaction over ZrO$_2$(8.9)–FeO$_X$ at 623 K, the yield of hydroxyacetone decreased, whereas the yields of carboxylic acids and aliphatic ketones increased.

In order to investigate the reaction mechanism, we carried out catalytic reactions using aqueous solutions of hydroxyacetone, carboxylic acids, and an aliphatic ketone as model compounds representing the pyroligneous acid. The yields of the main products from these reactions are listed in Table 3. Acetone was essentially inert during reaction over the ZrO$_2$–FeO$_X$ catalyst. Acetic and propionic acids were selectively converted into acetone and 3-pentanone, respectively. Moreover, hydroxyacetone was easily converted into acetic and propionic acids, which then further reacted to form acetone, 2-butane, and 3-pentanone via a ketonization process. The anticipated reaction routes for production of aliphatic ketones from hydroxyacetone and carboxylic acids over ZrO$_2$–FeO$_X$ can be seen in Fig. 3. Based on the product yields obtained from these model compounds and the reaction routes shown, the changes in the product yields shown in Fig. 2 were ascribed to a ketonization reaction of carboxylic acids in the pyroligneous acid that took place over the catalyst.

As shown in Fig. 2, the yield of gaseous products, mainly CO$_2$, increased considerably and the yield of heavy components decreased when the reaction temperature increased from 623 to 723 K. In the ketonization reaction, two molecules of carboxylic acids are converted into one molecule of ketone and CO$_2$. However, the amount of CO$_2$
generated during the reaction was larger than that calculated for the ketonization. Accordingly, the generation of CO₂ was ascribed to oxidation of the heavy components in the pyroligneous acid. Moreover, the product yield of aliphatic ketones gradually decreased with increasing reaction temperature, indicating that the aliphatic ketones produced from the carboxylic acids were oxidized at 673 and 723 K because of the high reaction temperatures.

XRD patterns of the ZrO₂(8.9)–FeOₓ catalyst prior to and after reactions at 623, 673, and 723 K are shown in Fig. 4. The patterns of the catalyst prior to and after the reaction at 623 K showed peaks corresponding to hematite (α-Fe₂O₃). The patterns of the catalysts after reaction at 673 and 723 K, in contrast, showed peaks corresponding to magnetite (Fe₃O₄). It was considered that the heavy and lighter components, as well as other chemicals, were oxidized using the lattice oxygen of iron oxide, where oxygen defects were formed within the hematite structure. The consumed lattice oxygen was regenerated by oxygen-active species that were produced on ZrO₂ by decomposition of H₂O molecules [10, 12]. At the high reaction temperatures of 673 and 723 K, excessive consumption of lattice oxygen occurred during the reaction, leading to the change in crystallinity of the catalyst from hematite to magnetite. Therefore, it was decided that 623 K was the appropriate reaction temperature.

3.3. Effect of ZrO₂ content in the catalyst on catalytic activity

In the pyroligneous acid, the light and heavy components derived from pyrolytic decomposition of cellulose were present at approximately 15 and 45 C mol%, respectively. It was considered that decomposition of the light and heavy components in the pyroligneous acid over the catalyst caused new production of hydroxyacetone and carboxylic acids, leading to an increase in the ketone yield because hydroxyacetone and carboxylic acids were source chemicals for ketone production, as shown in Fig. 3. On the other hand, the ZrO₂–FeOₓ catalysts possessed oxidative decomposition activity towards the heavy components using the lattice oxygen in FeOₓ, which was accelerated by adding ZrO₂ on the FeOₓ [9]. Moreover, the oxygen defects in the FeOₓ formed during the decomposition of the heavy components were regenerated by oxygen-active species produced from H₂O molecules over ZrO₂. Accordingly, the effects of ZrO₂ content on aliphatic ketone yield were examined and are presented in Fig. 5. As the ZrO₂ content increased, the yield of the heavy components decreased, and the yield of residue deposited on the catalyst increased. Since ZrO₂ possesses the properties of a solid acid, the increase in the amount of coke-like residue on the catalyst was ascribed to the increase in the ZrO₂ content. On the basis of the catalytic stability shown in Fig. 4 and the amount of coke-like residue on the catalyst shown in Fig. 5, the ZrO₂(8.9)–FeOₓ catalyst was determined to be an appropriate catalyst.

In our previous research, it was revealed that an increase in the amount of ZrO₂ in ZrO₂–FeOₓ catalysts enhances the catalytic activity to produce ketones from biomass-derived tar [8]. As shown in Fig. 5, the total yield of aliphatic ketones and carboxylic acids slightly increased with increasing amounts of ZrO₂ up to 50 wt.%. The yield of aliphatic ketones increased with increasing ZrO₂ content, whereas the yield of carboxylic acids decreased.
ketones was almost unchanged, however, regardless of ZrO$_2$ content. During pyrolysis of woodchips biomass, alkali and alkaline earth metals, essential metals contained in the biomass were released from the woodchips and dissolved in the pyrolygenous acid. XRF analysis of the pyrolygenous acid revealed that potassium (K) and magnesium (Mg) were present at concentrations of 580 and 430 ppm, respectively. Accordingly, it was considered that these metal impurities were deposited on the catalyst to de-activate the ketonization activity.

3.4. Removal of metal impurities and effect of W/F on ketone yields

As mentioned above, because it was considered that the metal impurities such as K and Mg were catalytic poisons and decreased catalytic activity, a cation-exchange resin was used to remove these metals from the pyrolygenous acid. After ion-exchange treatment using the cation-exchange resin, K and Mg were recognized as trace elements in the pyrolygenous acid by XRF analysis. The product yields after catalytic reactions over the ZrO$_2$(50)–FeO$_x$ catalyst are shown in Fig. 6. Pyrolygenous acids prior to and after cation-exchange treatment were used as feedstocks. The chemical compositions of the feeds are also shown in this figure for comparison.

Since the compositions of the pyrolygenous acids prior to and after cation-exchange treatment were almost unchanged, the metal impurities such as K and Mg were selectively removed from the pyrolygenous acid. Moreover, when using the pyrolygenous acid after removing the metal impurities, the yield of aliphatic ketones was increased as compared to the reaction with the pyrolygenous acid prior to the cation-exchange treatment. Accordingly, it was considered that these metal impurities reduced the catalytic activity for production of aliphatic ketones and hence the cation-exchange treatment to remove K and Mg from the pyrolygenous acid was effective in avoiding catalyst deactivation by the deposition of alkali and alkaline earth metals.

Next, the effect of catalyst weight (W/F value) on product yields was examined to determine if the yield of aliphatic ketones could be increased. Product yields from reactions over ZrO$_2$(8.9)–FeO$_x$ with different W/F values using the pyrolygenous acid without metal impurities (the pyrolygenous acid after cation-exchange treatment) can be seen in Fig. 7. Although more coke-like residue was deposited on the catalyst as the W/F value increased, the yield of light and heavy components decreased and the yield of aliphatic ketones increased. As discussed above, hydroxyacetone is converted into carboxylic acids and then two molecules of carboxylic acids produce one molecule of ketone. Aliphatic ketone yields were higher than expected, though, on the basis of the amount of hydroxyacetone and carboxylic acids in the pyrolygenous acid, as shown in Fig. 7. These results indicated that the decomposition of light and heavy components occurred using the lattice oxygen in FeO$_x$ to produce carboxylic acids, leading to the production of additional amounts of the aliphatic ketones from the carboxylic acids that were newly formed over the ZrO$_2$–FeO$_x$ catalyst. Accordingly, the ZrO$_2$–FeO$_x$ catalyst is an appropriate catalyst for producing aliphatic ketones from
pyrolyzineous acid derived from woody biomass. The maximum yield of aliphatic ketones reached approximately 30 C mol% at a W/F of 4 h, and the fraction of aliphatic ketones in the obtained liquid product reached 55 C mol%, with the main products consisting of 2-butanone (22 C mol%) and acetone (33 C mol%).

4. Conclusions

Catalytic reactions of organic-containing water solutions (pyrolyzineous acid) derived from slow pyrolysis of Japanese cedar woodchips were carried out in a fixed bed reactor using ZrO$_2$–FeO$_x$ catalysts. In this study, ZrO$_2$–FeO$_x$ was an appropriate catalyst with high activity for the selective production of ketones (acetone and 2-butanone) from the pyrolyzineous acid. The presence of metal impurities such as K and Mg in the pyrolyzineous acid, however, inhibited catalytic activity. Removal of the metal cations from the pyrolyzineous acid using a cation-exchange resin was effective, though, for maintaining catalytic activity for ketone production. The maximum ketone yield reached approximately 30 C mol% at a reaction temperature of 623 K and a W/F value of 4 h.
