Glutamate transporters are involved in neural differentiation, neuronal survival, and synaptic transmission. In the present study, we examined glutamate transporter 1 (GLT1) expression in the neonatal somatosensory cortex of C57BL/6 mice, and pursued its role in somatosensory development by comparing barrel development between GLT1 knock-out and control mice. During the first few neonatal days, a critical period for barrels, GLT1 expression is strikingly upregulated in cortical astrocytes, whereas it was downregulated in neuronal elements to below the detection threshold. GLT1 knock-out neonates developed normally in terms of body growth, cortical histoarchitecture, barrel formation, and critical period termination. However, when row C whiskers were lesioned during the critical period, reduction of lesioned row C barrels and reciprocal expansion of intact row B/D barrels were both milder in GLT1 knock-out mice than in control littersmates. Accordingly, the map plasticity index, calculated as [(B + D)/2C]−1, was significantly lowered in GLT1 knock-out mice. We also found that extracellular glutamate levels in the neonatal somatosensory cortex were significantly elevated in GLT1 knock-out mice. Diminished lesion-induced plasticity was further found in mutant mice lacking glutamate–aspartate transporter (GLAST), an astrocyte-specific glutamate transporter throughout development. Therefore, glutamate transporters regulate critical period plasticity by enhancing expansion of active barrels and shrinkage of inactive barrels. Because cortical contents of glutamate receptors and GLAST were unaltered in GLT1 knock-out mice, this action appears to be mediated, at least partly, by keeping the ambient glutamate level low. Considering an essential role of glutamate receptors in the formation of whisker-related thalamocortical synapse patterning, glutamate transporters thus facilitate their activity-dependent remodeling.

Key words: glutamate transporter; barrel; somatosensory; development; critical period; plasticity; mouse

Introduction
Whiskers are tactile hairs on the face of nonhuman mammals (Munger and Ide, 1988) and are topographically represented as modular patterns at somatosensory stations of rodents (Wooley and Van der Loos, 1970). Whisker-related patterns are referred to as barrels in the somatosensory cortex, barreloids in the thalamus, and barrelettes in the brainstem. The development of these patterns is altered by peripheral lesions during early neonatal days known as the critical, or sensitive, period, and then consolidated as permanent structures. If sensory nerves innervating whisker follicles are completely severed during the critical period, the central patterns are blurred or fused (Weller and Johnson, 1975; Belford and Killackey, 1980; Chiaia et al., 1992; Yamakado, 1995; Toki et al., 1999). When particular whiskers are lesioned during the critical period, lesioned barrels shrink in the somatosensory cortex and adjacent intact barrels expand reciprocally; this process is termed lesion-induced plasticity (Van der Loos and Woolsey, 1973; Killackey et al., 1976; Woolsey and Wann, 1976; Jeannodon et al., 1977). Through this activity-dependent process, crude sensory maps are refined and remodeled into functional ones that match with the peripheral receptor surface in a point-to-point manner. Analyses of gene-engineered mice have addressed that glutamatergic signalings through the NMDA-type receptor and metabotropic glutamate receptor 5 (mGluR5) play an essential role in the formation of whisker-related central patterns (Li et al., 1994; Fox et al., 1996; Kutsuwada et al., 1996; Iwamoto et al., 1997, 2000; Hannan et al., 2001).

Extracellular glutamate concentration has to be kept low enough to terminate glutamate receptor activation and to protect neurons from excitotoxicity by means of high-affinity glutamate transporters on the cell membrane (Hertz, 1979; Choi, 1992). Glutamate transporter 1 (GLT1) and glutamate–aspartate transporter (GLAST) are the predominant astrocytic glutamate transporters with relative abundance in the telencephalon or cerebellum, respectively, of adult animals (Danbolt, 2001). Subse-
Quently, GLT1 has been shown to be expressed in neuronal elements transiently during embryonic stages (Furuta et al., 1997; Yamada et al., 1998; Northington et al., 1999), although a particular splice form of GLT1 was reported to be expressed in adult brains (Chen et al., 2002, 2004; Schmitt et al., 2002; Berger et al., 2005). Previous reports have demonstrated physiological roles of these transporters in neuronal differentiation and survival, synaptic transmission and plasticity, and metabolic cross talk between neurons and glia (Tanaka et al., 1997; Watase et al., 1998; Katagiri et al., 2001; Voutsinos-Porche et al., 2003; Takayasu et al., 2005, 2006; Matsugami et al., 2006). Little is known, however, about their role in activity-dependent synapse development, through which cortical circuits attain functional and anatomical maturity (O’Leary et al., 1994; Singer, 1995; Crair, 1999).

In the present study, we investigated the role of glutamate transporters in barrel development. We found that barrel formation and critical period termination occurred normally in the somatosensory cortex of GLT1 knock-out (KO) mice, but their lesion-induced plasticity was significantly diminished compared with control litters. Reduced plasticity was also observed in GLAST-KO mice. These findings suggest that glutamate transporters facilitate activity-dependent remodeling of somatosensory maps during the critical period.

Materials and Methods

Animals. Mouse pups were obtained from breeding pairs of C57BL/6 wild-type mice for expression analysis, and from pairs of heterozygous GLT1 (Tanaka et al., 1997), GLAST (Watase et al., 1998), and mGlur5 (stock 003558; The Jackson Laboratory, Bar Harbor, ME) mutant mice for barrel analyses. Mice were treated according to the guidelines for the care and use of laboratory animals of the Hokkaido University School of Medicine and Kyoto University. The day after overnight mating was counted as embryonic day 0 (E0), and only pups born on the 19th day of gestation were used. The day of birth (~24 h) was designated as postnatal day 0 (P0). Genotyping of genomic tail DNA by PCR and phenotypic analyses on barrel development were performed in a blind manner. Under deep pentobarbital anesthesia (100 mg/kg of body weight, i.p.), mice were fixed by transcardial perfusion with 4% paraformaldehyde/0.1% picric acid in 0.1 M sodium phosphate buffer (PB), pH 7.2. Sections for histochemical and immunohistochemical analyses were prepared using a microtome (40 μm thick) or cryostat (30 μm).

Antibody. We used rabbit GLT1 antibody (1 μg/ml; GLT1/1 raised against 500–525 aa) (Yamada et al., 1998), guinea pig GLAST antibody (1 μg/ml) (Shibata et al., 1997), mouse microtubule-associated protein-2 (MAP2) antibody (4 μg/ml; no. 1284959; Roche Diagnostics, Mannheim, Germany), mouse neurofilament antibody 160 (1:100; N264; Sigma-Aldrich, St. Louis, MO), guinea pig type 2 vesicular glutamate transporter (VGluT2) antibody (1 μg/ml) (Miyazaki et al., 2003), and guinea pig or rabbit mGlur5 antibody (1 μg/ml) (Uchigashima et al., 2007). To detect AMPA-type glutamate receptors, a mixture of rabbit GluR1 and GluR2 antibodies (1 μg/ml each) was used (Shimuta et al., 2001).

Immunohistochemistry. All incubations were performed at room temperature. After overnight incubation with the primary antibody, sections were incubated with fluorescein isothiocyanate (FITC)- or indocarbocyanine (Cy3)-conjugated species-specific secondary antibodies for 2 h (Jackson ImmunoResearch, West Grove, PA). Stained sections were photographed using a confocal laser-scanning microscope (FV1000; Olympus Optical, Tokyo, Japan). For preembedding silver-enhanced immunogold staining, microslicer sections were dipped in 3% bovine serum albumin (BSA)/0.02% saponin/PBS for 30 min and incubated overnight with GLAST or mGlur5 antibody diluted with 1% BSA/0.004% saponin/PBS followed by anti-rabbit IgG linked to 1.4 nm gold particles (Nanogold; Nanoprobes, Stony Brook, NY) for 2 h. Immunogold staining was intensiﬁed with a silver enhancement kit (HQ silver; Nanoprobes). Then, sections were treated with 2% osmium tetroxide for 30 min, stained in blocks with 2% uranyl acetate for 30 min, dehydrated, and embedded in Epon 812.

Immunoblot. Homogenates of P2 cerebral cortex (n = 3 each for GLT1-KO and control mice) were prepared by sonication in ice-cold buffer containing 10 mM Tris–HCl, pH 7.6, 20 mM KC1, 1 mM EDTA, 1 mM EGTA, and 0.25 M sucrose. Protein concentration was determined by the Lowry’s method. Protein samples (40 μg) were separated by 7.5% SDS-PAGE under reduced conditions, and electroblotted onto a nitrocellulose membrane (Whatman, Dassel, Germany). The membrane was immunoreacted with the following primary antibodies for 2 h: GLT1 antibody, GLAST antibody, mGlur5 antibody, and a mixture of GluR1 and GluR2 antibodies (1 μg/ml for each). Immunoreactions were visualized using the ECL detection system (GE Healthcare, Little Chalfont, Buckinghamshire, UK). For semiquantification, gray levels of protein bands on films were measured using IPLab software (Nippon Roper, Tokyo, Japan), and β-actin was used as an internal standard for comparison. Student’s t test was used for statistical comparisons.

Barrel analyses. Barrels were visualized by cytochrome oxidase (CO) histochemistry (Wong-Riley, 1979). The right infraorbital nerve (ION) was transected to determine when the critical period terminated. Under hypothermia-induced anesthesia, a vertical slit was made just behind the mystacial pad to expose the right ION. The ION was cut with a pair of iridectomy scissors, the cut edge was subjected to electrical cautery to prevent nerve regeneration, and then pups were returned to their mothers. After 8 d, mice were anesthetized by pentobarbital (100 mg/kg of body weight) and killed for CO histochemistry. Optical density was measured along two crossing lines through C1, C2, and C3 barrels and through B2, C2, and D2 barrels. Developmental appearance and critical period termination were judged only when all these barrels were visibly segregated and the summed relative density for each measured barrel exceeded 20,000 arbitrary units (supplemental Fig. S1, available at www.jneurosci.org as supplemental material). To compare genotypic differences, we estimated the age when barrels appeared in 50% of mice (DA50) and the age when the critical period was terminated in 50% of mice (CPT50). To obtain the optimal DA50 and CPT50 values and their 95% confidence intervals, probit regression analysis was used (Finney, 1971); the fraction of mice that had formed barrels or completed the critical period was converted into probits at each postnatal age. Probit-fitted linear regression lines were used for calculation. Differences between control and mutant DA50 or CPT50 values were considered statistically significant, if there was no overlap between their confidence intervals. Fisher’s exact probability test was used for statistical evaluation. To compare the size of barrels, the area of C2/C3 barrels was also measured.

Row C whiskers were lesioned to compare critical period plasticity. For four rows of the right row C whiskers were catarozied at P0, P2, or P4, and CO histochemistry and immunofluorescence were performed on P15. Whisker pads were examined stereoscopically and histologically to verify the absence of regrowth. Area measurements were performed with IPLab software (Nippon Roper) for a pair of barrels in each row (A2/A3, B2/B3, C2/C3, D2/D3, or E2/E3) including their intervening septa. In measurement of fused, lesioned row C barrels, the extent of C2/C3 barrels was defined by the location of adjacent B2/B3 and D2/D3 barrels. From the scores, we calculated the ratio of row C or row B/D to the total measured area and the map plasticity index (MPI). Statistical differences were measured with the Mann–Whitney U test.

Patterning of cortical neurons and thalamocortical afferent terminals was examined by Nissl staining with NeuroTrace 500/525 green fluorescent Nissl stain (Invitrogen, Carlsbad, CA) and VGluT2 immunofluorescence, respectively.

Brain microdialysis. P3 GLT1 mice were anesthetized with a mixture of 1.0% halothane and nitrous oxide/oxygen (7:3). The head of the animal was held with surgical tape in a stereotaxic apparatus (type 1430; David Kopf, Tujunga, CA). Burholes for probe insertion were made and the dura was carefully incised.

A thermocouple needle-probe of 0.4 mm diameter (TN-800S; Unique Medical, Tokyo, Japan) and a thermocouple meter (TME-300; Unique Medical) were used to monitor brain temperature. The thermocouple probe was inserted in the right cortex (1.8–2.2 mm rostral to the L, 1.8–2.2 mm posterior to the M.)
Figure 1. Specificity of GLT1 immunohistochemistry in developing mouse brains. **A**, Immunoperoxidase staining of paraffin sections from P9 mice. The absence of staining in the GLT1-KO brain section (bottom) indicates the specificity of immunostaining in the control brain section (top). **B, C**, Immunofluorescence in the P4 somatosensory cortex with use of GLT1 antibody in the absence (B) or presence (C, i.e., absorbed GLT1 antibody) of antigen peptide. **D**, GLT1 immunoblot of brain extracts from control (+/+) and GLT1-KO (−/−) mice. Scale bars: **A**, 1 mm; **B, C**, 100 μm.

Results

GLT1 is upregulated in cortical astrocytes during early neonatal days

Using GLT1 antibody raised against the sequence common to all known splice variants (Rauen et al., 2004), we first examined temporal profile of GLT1 expression in the neonatal somatosensory cortex of C57BL/6 mice. The specificity of GLT1 antibody and immunohistochemistry was verified by blank immunohistochemical and immunoblot labeling in GLT1-KO brains (Fig. 1A–K) and with use of GLT1 antibody preabsorbed with the antigen (Fig. 1B, C).

Because the lamina IV of the somatosensory cortex comes into existence at P3 (Agnon et al., 1993), we examined the cortical plate overlying the lamina V at P0 (Fig. 2A–F) and P2 (Fig. 2G–L), and the lamina IV at P3 (Fig. 2M–R) and P4 (Fig. 2S–W), using Nissl-stained adjacent sections as references for cortical layers (Fig. 2A,G,M). At P0, GLT1 staining was most intense in the early-differentiating lamina VI and least intense in the late-differentiating cortical plate (Fig. 2A,B). Within the cortical plate, GLT1 was detected in various neuronal elements, including neurofilament-positive axons (Fig. 2C), VGluT2-positive glutamatergic terminals (Fig. 2D), and MAP2-positive dendrites (Fig. 2E), whereas it overlapped only partially with GLAST-positive glial elements (Fig. 2F). The overlap of GLT1 with GLAST increased substantially at P2 (Fig. 2L) and became almost complete at P3 (Fig. 2R). Simultaneously, GLT1 became undetectable in axons and terminals by P2 (Fig. 2L–K), and dendrites by P3 (Fig. 2Q). At P4, GLT1 displayed remarkable upregulation in GLAST-positive glial elements (Fig. 2T–W), displaying barrel-like appearance by GLT1 immunofluorescence (Fig. 2S). In the neonatal period from P0 to P4, GLT1 is thus downregulated in neuronal elements to below the detection threshold, and is strikingly upregulated in cortical astrocytes.

Interestingly, the accomplishment of GLT1 switching at around P3 appears to corresponds to the stages for whisker-related patterning of thalamocortical afferents (i.e., barrel formation) (Senft and Woolsey, 1991; Rebsam et al., 2002) and for loss of lesion-induced plasticity (Van der Loos and Woolsey, 1973; Woolsey and Wann, 1976; Jeannin and Wolfer, 1981), although the two developmental events are not causally linked (Rebsam et al., 2005).

Role of GLT1 in barrel development

The role of GLT1 in somatosensory development was pursued in the somatosensory cortex by comparing the stage of barrel appearance (formation), the stage of critical period termination, and the magnitude of lesion-induced plasticity in GLT1-KO and control littermates. Body weight (in grams) did not differ significantly between GLT1-KO and control littermates at P0 [1.4 ± 0.2 (n = 19) vs 1.5 ± 0.2 (n = 19)], P4 [3.2 ± 0.1 (n = 7) vs 3.2 ± 0.4 (n = 6)], and P15 [7.0 ± 0.9 (n = 21) vs 7.0 ± 1.1 (n = 13)] (mean ± SD; p > 0.05 for each time point, Student’s t test).
indicating that GLT1-KO mice grew normally until P15. This is consistent with our previous report (Tanaka et al., 1997).

**Barrel appearance**

CO histochemistry was performed at P2–P5 (Fig. 3A–H). Five rows of large barrels in the posterior barrel subfield, which correspond to long mystacial whiskers on the snout, were invisible, obscure, or not fully segregated at P2 and P3 in any GLT1-KO or control mice. By using densitometric measurement for the judgment of barrel appearance (supplemental Fig. S1, available at www.jneurosci.org as supplemental material), we confirmed that barrels appeared in none of GLT1-KO and control mice at P2 and P3 (Fig. 4A and B). The percentage of mice that had completed the critical period was thus not terminated in these mice at P2 (see Fig. 6A). The percentage increased to 64 and 75% in GLT1-KO and control mice, respectively (Fig. 4C), showing no significant difference (Fisher’s exact probability test, p > 0.05) at P5, showing comparable barrel development in GLT1-KO mice.

**Critical period termination**

After transection of the right ION, lesioned (contralateral) and intact (ipsilateral) cortices were examined by CO histochemistry 8 d later (Fig. 4A–H). CO intensity was diminished in lesioned barrels, and barrels were blurred and fused into continuous rows in all GLT1-KO and control mice lesioned on P2 (Fig. 4A, D1). The critical period was thus not terminated in these mice at P2 (see Fig. 6B). Separation into individual barrels was still incomplete in the majority of GLT1-KO and control mice lesioned on P3 (Fig. 4C, D2): the percentage of mice that had completed the critical period was 30 and 25%, respectively. The percentage increased to 93 and 92% in P4-lesioned GLT1-KO and control mice, respectively (Fig. 4E, F1), and was 100% in both genotypes lesioned on P5 (Figs. 4G, H, 6B). The age at which the critical period was terminated in 50% of mice (CPTs) was calculated to be P3.2 (95% confidence interval, P2.8–P3.5) in GLT1-KO mice and P3.3 (P2.9–P3.7) in control mice, showing no significant difference (p > 0.05). No apparent changes were observed in the intact cortex (Fig. 4A, H2).
Lesion-induced plasticity
To examine lesion-induced plasticity during the critical period, hair follicles of right row C whiskers were electrocauterized at P0, P2, and P4. Changes in barrel map structure were examined by CO histochemistry at P15 (Fig. 5A–F). When row C hair follicles were lesioned on P0 and P2, row C barrels in the lesioned cortex were diminished in size and fused into a continuous row, whereas adjacent row B and row D barrels expanded reciprocally in both GLT1-KO and control mice (Fig. 5A–D). However, the extents of reduction in lesioned barrels and reciprocal expansion in intact barrels were both milder in GLT1-KO mice than in control mice (Fig. 5F). No such changes were observed by P4 lesion in either type of mice (Fig. 5E,F).

This phenotypic change was quantified by measuring the area of A2–A3, B2–B3, C2–C3, D2–D3, or E2–E3 barrels. After lesion on P0 or P2, the ratio of the C2–C3 area relative to the total measured area was significantly greater in GLT1-KO mice than in control mice (p < 0.01 for each, Mann–Whitney U test) (Fig. 6C). No such difference was observed in mice lesioned on P4 (p > 0.05). Conversely, the ratio of the summed B2–B3 and D2–D3 areas relative to the total measured area was significantly lower in GLT1-KO mice than in control mice lesioned on P0 or P2 (p < 0.01 for each), but not in mice lesioned on P4 (p > 0.05) (Fig. 6D). Consequently, the MPI, as obtained from (B2 + B3 + D2 + D3)/(2(C2 + C3)), was significantly lower in GLT1-KO mice than in control mice lesioned on P0 or P2: 1.61 ± 0.34 (n = 11; mean ± SD) versus 3.80 ± 2.21 (n = 8) by P0 lesion and 1.34 ± 0.21 (n = 10) versus 2.79 ± 1.79 (n = 10) by P2 lesion, respectively (p < 0.01 for each) (Fig. 6E). No significant differences in the MPI were observed in the cortex from mice lesioned on P4 [0.99 ± 0.05 (n = 9) vs 0.99 ± 0.02 (n = 7); p > 0.05] or in the intact cortex (p > 0.05 for each) (Fig. 6E).

Therefore, lesion-induced plasticity was significantly reduced in GLT1-KO mice. Furthermore, normal temporal closing of the critical period (i.e., by P4 in both genotypes) was confirmed again by row C whisker lesion experiment.

Presynaptic and postsynaptic patterning of thalamocortical synapses
CO intensity reflects mitochondrial enzymatic activity in both presynaptic and postsynaptic elements (Wong-Riley and Welt, 1980). To visualize the patterning of presynaptic and postsynaptic elements, double fluorescent labeling was used: VGluT2 immunofluorescence for thalamocortical afferent terminals and Nissl staining for neuronal arrangement. In both types of mice, thalamocortical terminals were clearly clustered, but neuronal patterning was still somewhat obscure at P5 (data not shown). At P6, neuronal somata in the lamina IV clustered into the barrel septae, and surrounded thalamocortical terminal clusters in GLT1-KO and control mice (Fig. 3I–L). In mice subjected to ION transection on P5, presynaptic and postsynaptic patterns were maintained in the lesioned cortex of both genotypes (Fig. 4I–L). These results confirm that both patterns are normal in terms of whisker-related patterning and critical period termination in GLT1-KO mice.

Normal cortical cytoarchitecture, GLAST levels, and glutamate receptor levels in GLT1-KO neonates
To clarify the origin of the reduced plasticity, mice whose row C whiskers were lesioned on P2 were subjected to double labeling for VGluT2 and metabotropic glutamate receptor mGluR5 (Fig. 5G–J) or Nissl staining (Fig. 5K–N). mGluR5 was used to examine dendritic patterning of cortical neurons, because it is exclusively expressed on dendrites and spines in adult rodents (Shigemoto et al., 1993; Lujan et al., 1996), and this was also true in the neonatal somatosensory cortex (supplemental Fig. S2, available at www.jneurosci.org as supplemental material). In the lesioned side of GLT1-KO and control mice, VGluT2 and mGluR5 immunofluorescences were detected in hollows of fused row C barrels in a spatially matched manner (Fig. 5G–J). Moreover, cortical neurons of row C barrels were arranged at the border with row B and row D barrels, and surrounded VGluT2-stained fused thalamocortical pattern (Fig. 5K–N). Again here, milder reduction of lesioned row C barrels was reproduced in GLT1-KO mice. Therefore, the reduced cortical plasticity in GLT1-KO mice involves presynaptic, neuronal, and dendritic elements in the lamina IV.

Normal cortical cytoarchitecture, GLAST levels, and glutamate receptor levels in GLT1-KO neonates
To seek possible reasons for altered plasticity, we compared the histochemistry and expression of glutamatergic signaling molecules between GLT1-KO and control neonates (Fig. 7A–N). In P0 GLT1-KO mice, no apparent differences were discernable in the histoarchitecture of the somatosensory cortex, in which the laminae I, V, and VI, but not II–IV, were differentiated (Fig. 7A–D). Likewise, similar patterns and intensity were noted by immunohistochemistry for neurofilament, VGluT2, MAP2, and GLAST (Fig. 7E–L). At P2, GLAST was detected selectively in astrocytic elements in both GLT1-KO and control mice (Fig. 7M,N). By immunoblot using P2 cortical homogenates, comparable protein...
levels were observed for GLAST (100.0 ± 4.2 and 111.1 ± 16.7% in control and GLT1-KO; mean ± SD), AMPA receptors as detected with a mixture of GluR1 and GluR2 antibodies (100.0 ± 10.5 and 117.5 ± 2.2%), the NMDA receptor NR1 subunit (100.0 ± 10.4 and 114.4 ± 18.2%), and mGluR5 (100.0 ± 4.9 and 101.6 ± 9.1%) (p > 0.05 and n = 3 for each, Student’s t test) (Fig. 7O). Therefore, GLT1-KO neonates are normal in histarchitectonic development of the somatosensory cortex and in cortical contents of GLAST and glutamate receptors. This is consistent with a previous study showing unchanged protein levels of GLAST and NMDA receptor NR2A/B subunits in the cortex of P10 GLT1-KO mice (Voutsinos-Porche et al., 2003).

Elevated extracellular glutamate level in the somatosensory cortex of GLT1-KO neonates

Because glutamate transporters play a key role in keeping the extracellular glutamate concentration low, we used microdialysis to address whether the lack of GLT1 affects extracellular glutamate levels in the somatosensory cortex of P3 mice. The genotyping revealed that, of 18 mice examined, 5 were GLT1-KO mice, 8 were GLT1-heterozygous mice, and 5 were control mice. Histological examinations confirmed that 0.5-mm-long microdialysis membranes were located in the somatosensory cortex. An acute increase in extracellular glutamate levels was observed immediately after insertion of the probe regardless of the genotype; this is attributable to the efflux of intracellular glutamate mainly from neurons damaged by probe insertion. Extracellular glutamate levels decreased to stable low levels within 30 min of probe insertion. The average value of six samples collected consecutively from 30 to 60 min after probe insertion was calculated to evaluate extracellular glutamate levels in each animal. Extracellular glutamate levels in GLT1-KO mice (n = 5) were significantly higher than those in control mice (n = 5) (p = 0.017; one-way ANOVA; Scheffe’s post hoc test) (Fig. 7P). Extracellular glutamate values in GLT1-KO mice also tended to be higher than those in GLT1-heterozygous mice (n = 8), but the difference was not statistically significant (p = 0.087). The ablation of GLT1 thus leads to elevated extracellular glutamate level in the somatosensory cortex of GLT1-KO neonates.

Lesion-induced plasticity is also reduced in GLAST-KO mice

If reduced glutamate uptake function is involved in reduced plasticity, the lack of GLAST could also cause the similar effect, although its expression and functional contribution in the cortex are lower than those by GLT1 (Lehr et al., 1995; Tanaka et al., 1997). To test this possibility, we lesioned row C whiskers of mutant mice lacking GLAST by giving electrocautery to row C follicles at P2 and CO histochemistry at P15. The reduction in the MPI in GLAST-KO mice (1.30 ± 0.22; n = 9; mean ± SD) was significantly less than that in control littermates (1.92 ± 0.61; n = 12) (Figs. 6F, 8A,B) (p < 0.01; Mann-Whitney U test). No significant difference was observed in intact cortex (0.96 ± 0.02 in GLAST-KO and 0.96 ± 0.03 in control; p > 0.05). Therefore, critical period plasticity is reduced in GLAST-KO mice as well, favoring the notion that glutamate uptake function is important for lesion-induced plasticity.

Discussion

Glutamate transporters selectively magnify lesion-induced plasticity

GLT1-KO mice normally gained the body weight until P15. No apparent differences were noted in the histarchitecture of the somatosensory cortex and in cortical contents of GLAST and glutamate receptors in GLT1-KO neonates. Furthermore, tem-
poral profile of barrel development was normal in terms of barrel appearance and critical period termination. Thus, the reduced plasticity in GLT1-KO mice is unlikely to result from general defects in body growth or brain development. GLT1-KO mice are known to start dying suddenly from intractable seizures in the third postnatal week (Tanaka et al., 1997), raising the possibility that the epileptogenic properties could affect the plasticity. However, there is little, if any, possibility of this, because the plasticity is also reduced in GLAST-KO mice, a nonepileptogenic model that normally grows and survives (Watase et al., 1998). Moreover, comparable size of CO-stained C2–C3 barrels at P4 and P5 suggests that thalamocortical afferents subserving row C barrels maintain their ability to expand in both GLT1 and control mice. Taking that GLAST is highly expressed in astrocytes throughout development (Shibata et al., 1997) (Fig. 1) and that abundant GLT1 is provided to cortical astrocytes during the critical period, these transporters likely cooperate to magnify the lesion-induced plasticity in the somatosensory cortex. This molecular function will facilitate developmental remodeling of somatosensory maps in an activity-dependent manner.

Glutamate transporters and receptors play distinct roles in barrel development

NMDA receptors and group I mGluRs (mGluR1 and mGluR5) mediate activity-dependent Ca²⁺ influx and release, respectively, and trigger long-term potentiation and depression of synaptic transmission (Bliss and Collingridge, 1993; Aiba et al., 1994; Conquet et al., 1994; Bear, 1996). Both forms of synaptic plasticity can be readily elicited at thalamocortical synapses during the critical period, and are thought to regulate activity-dependent synaptic refinement (Crair and Malenka, 1995; Feldman et al., 1998; Barth and Malenka, 2001). Indeed, whisker-related patterning of thalamocortical synapses is impaired in mice defective for the NR1 (GluR1) subunit of NMDA receptors, mGluR5, and its effector enzyme type-1 phospholipase Cβ (PLCβ) (Li et al., 1994; Iwasato et al., 1997, 2000; Hannan et al., 2001). Of these, molecular ablation is proved specific to the postsynaptic (cortical) side of thalamocortical synapses in cortex-specific NR1-KO mice (Iwasato et al., 2000). This study has provided the evidence that cortical patterning is completely lost in the mutant mice despite the presence of thalamocortical patterning, although smaller in size and less sharply defined than control mice. Mutant mice lacking mGluR5 or PLCβ1, which are predominantly expressed in the cortex but very low in the thalamus (Testa et al., 1995; Watanabe et al., 1998) (supplemental Fig. S2, available at www.jneurosci.org as supplemental material), manifest similar phenotypes (Hannan et al., 2001). Considering that thalamocortical projections are patterned earlier than postsynaptic neurons (Ercal and Jhaveri, 1990; Schlaggar and O'Leary, 1994), signaling through these glutamate receptors translate patterned presynaptic activity into subsequent postsynaptic patterning, leading to the formation of whisker-related somatosensory maps.

Because glutamate transporters control glutamate receptor-mediated synaptic transmission and plasticity (Katagiri et al., 2001; Wadiche and Jahr, 2005; Takayasu et al., 2005, 2006), we had surmised before experiments that phenotypes of glutamate transporter-defective mice might approximate those in mutant mice lacking glutamate receptors. However, whisker-related patterns were formed normally, and presynaptic and postsynaptic patterns were normally differentiated in GLT1-KO mice. Instead, we found reduced lesion-induced plasticity in GLT1-KO and...
GLAST-KO mice, which contrasts with normal plasticity in cortex-specific NR1-KO (Iwasato et al., 2000; Datwani et al., 2002) and mGluR5-KO (Fig. 8C,D) mice. Thus, the different phenotypes have eventually highlighted their distinct roles in barrel development; glutamate receptors play an essential role in whisker-related topographical patterning of somatosensory synapses, whereas glutamate transporters facilitate their remodeling. Armed with both machineries, crude somatosensory maps can be normally refined and reorganized into functional ones during the critical period.

GLT1 switching during critical period is a general phenomenon in somatosensory stations

Predominant astrocytic expression of GLT1 in the adulthood (Chaudhry et al., 1995) is preceded by neuronal expression in the fetal and neonatal cerebellum and spinal cord (Furuta et al., 1997; Yamada et al., 1998; Northington et al., 1999). In the present study, we documented this in the somatosensory cortex, and have demonstrated that GLT1 switching proceeds during the critical period when synaptic circuits are highly plastic and sensitive to external stimuli. This prompted us to further examine GLT1 switching in subcortical relay nuclei. Switchover to predominant astrocytic expression was accomplished by P6 in the subnucleus interstitialis of the trigeminal spinal nucleus (Sp1) (supplemental Fig. S3, available at www.jneurosci.org as supplemental material), P3 to P5 in the trigeminal principal sensory nucleus (Pr) (supplemental Fig. S4, available at www.jneurosci.org as supplemental material), and P2 in the ventrobasal thalamus (VB) (supplemental Fig. S5, available at www.jneurosci.org as supplemental material).

Intriguingly, these stages correspond to the stages when critical period is terminated at each somatosensory station of mice: P5–P8 in the Sp5I, P3 in the Pr, and P2–P3 in the VB (Woolsey et al., 1979; Durham and Woolsey, 1984; Chiaia et al., 1992; Toki et al., 1999). Therefore, neuron-to-astrocyte switching of GLT1 expression occurs around the critical period at each somatosensory station, suggesting its potential involvement in synaptic circuit development at the subcortical levels too.

Postulated mechanisms of glutamate transporter-mediated lesion-induced plasticity

How can glutamate transporters regulate lesion-induced plasticity? Four possible mechanisms are discussed below.

Astrocytic glutamate transporters play a major role in rapid and bulk uptake of extracellular glutamate (Takayasu et al., 2005), and this function is further facilitated by coexpression of glutamine synthetase that converts glutamate to glutamine (Ercinska and Silver, 1990). Despite normal expression of GLAST, extracellular glutamate levels were significantly elevated in the somatosensory cortex of GLT1-KO neonates. Although cortical contents of glutamate receptors were not changed, the chronic elevation of ambient glutamate levels could affect presynaptic release function and postsynaptic activation. Indeed, blocking of glutamate transporters in immature neocortex and hippocampus generates recurrent NMDA receptor-mediated currents associated with synchronous Ca\(^{2+}\) oscillations in the entire neuronal population (Kidd and Isaac, 2000; Demarque et al., 2004; Cattani et al., 2007; Milh et al., 2007). Elevated glutamate levels could also affect synaptic competition so that inactive afferents can even activate postsynaptic targets substantially, as active afferents do. In this regard, the mechanisms that maximize such “activity discriminator” function should magnify lesion-induced plasticity, and factors that shift from the optimal point.

Figure 6. Quantitative comparisons in developmental appearance (A), critical period termination (B), and lesion-induced plasticity (C–F) of cortical barrels between GLT1-KO and control mice. A, B. The percentage of mice having cortical barrels (A) and the percentage of mice in which the critical period is terminated (B) increase with age in both GLT1-KO (black bars) and control (gray bars) mice. C, D. The ratio of the row C (C2/H11001) to row B/D (B2/H11001) area (D) relative to the total measured area (A2/H11001 of row C3) in GLT1-KO (circles) and control (squares) mice. The filled and open symbols indicate the lesioned or intact side, respectively. E, F. The map plasticity index (B2 + B3 + D2 + D3/C2 + C3) in GLT1-KO (E) and GLAST-KO (F) mice and their littermate controls. The black bars and gray bars indicate the lesioned and intact side, respectively. Error bars represent SEM. The numbers on the bars indicate the total number of mice examined at each stage. *p < 0.01.
would blunt the plasticity. Apparent normal plasticity in cortex-specific NR1-KO and mGluR5-KO mice suggests that other molecular machineries, whose function is fueled by glutamate transporters, should fulfill this role. We hypothesize that non-NMDA-type glutamate receptors are the possible candidate, because Schlaggar et al. (1993) have demonstrated that lesion-induced cortical plasticity is diminished by pharmacological blockade with high concentrations of D-2-amino-5-phosphovaleric acid that sufficiently silence AMPA receptor-mediated cortical excitation as well as NMDA receptor-mediated one. Therefore, the first mechanism is that glutamate transporters regulate lesion-induced plasticity through modulation of non-NMDA receptor activation.

Lesion-induced plasticity is also reduced by depletion of cholinergic neurons (Bear and Singer, 1986; Zhu and Waite, 1998; Nishimura et al., 2002). Moreover, elevated extracellular serotonin levels impair branch elaboration and collateral retraction of thalamocortical afferents (Cases et al., 1996; Vitalis et al., 1998; Young-Davies et al., 2000; Rebsam et al., 2002), although the extracellular serotonin level per se is unlikely to affect the plasticity (Rebsam et al., 2005). Considering the facts that muscarinic acetylcholine receptors modulate synaptic plasticity at glutamatergic synapses (Anagnostaras et al., 2003; Shinoe et al., 2005) and that 5-HT1B serotonin receptor on thalamocortical afferents strongly inhibits their synaptic transmission (Bennett-Clarke et al., 1993; Rhoades et al., 1994; Lotto et al., 1999; Laurent et al., 2002), functional interplay between glutamatergic and other signalings seems important for lesion-induced plasticity. Thus, the second mechanism is that their altered balance caused by glutamate transporter deficits might interfere with the plasticity.

When synaptic glutamate release is increased, obligatory Na+ influx coupled with glutamate transport enhances glucose utilization, glycogenolysis, and lactate release in astrocytes (Magistretti et al., 1999). This energy substrate is then supplied to nearby neurons and synapses to maintain their activity (Voutsinos-Porche et al., 2003). Thus, the third mechanism is activity-dependent metabolic support by glutamate transporters, which might allow astrocytes in active barrels to supply more energy substrate, and thereby promote the growth and expansion of active synaptic circuits.

In subcortical relay nuclei of the somatosensory system, ION lesion induces neuronal death during the critical period, whereas...
Figure 8. Lesion-induced plasticity is diminished in GLAST-KO mice (A, B), but normal in mGluR5-KO mice (C, D). CO histochemistry was performed on P15 after row C whisker follicle cautery at P2 in KO (A, C) and control (B, D) mice. In mGluR5-KO and control mice, the map plasticity index in the lesioned [1.45 ± 0.04 (n = 6) vs 1.44 ± 0.15 (n = 12)] and intact [0.93 ± 0.05 (n = 6) vs 0.97 ± 0.05 (n = 12)] cortices did not differ significantly between mGluR5-KO and control mice (Mann–Whitney U test, p > 0.05 for each). Note that CO patterns are slightly blurred in lesioned and intact cortices of mGluR5-KO mice compared with control mice, likely because of impaired postsynaptic patterning in this mutant (Hannan et al., 2001). As to reduced map plasticity index in GLAST-KO mice, see Figure 6 F. The lesioned cortex is shown on the left (e.g., A1) and the intact cortex is shown on the right (A2) for each mouse. Letters a–e indicate five rows of cortical barrels. Scale bar, 100 μm.

neuronal loss is prevented by NMDA receptors and neurotrophins (Sugimoto et al., 1999; Baldi et al., 2000; de Rivero Vaccari et al., 2006). Considering that GLT1 is upregulated and switched to astrocytes in developing subcortical stations, the fourth mechanism is that elevate glutamate levels in GLT1-KO mice could reduce neuronal death in subcortical relay nuclei and thereby diminish lesion-induced plasticity in the somatosensory cortex. The role of subcortical relay nuclei has been also implied from normal occurrence of lesion-induced plasticity in the absence of barrel formation (Rebsam et al., 2005). These hypothetical mechanisms need to be tested in future studies.

In conclusion, glutamate transporters regulate lesion-induced plasticity in the developing somatosensory cortex by enhancing expansion of intact or active barrels and minimizing lesioned or inactive barrels in early postnatal life.
