Abstract. Ambient aerosol samples (TSP, $n = 50$) were collected for 12 months at subtropical Okinawa Island, Japan, an outflow region of Asian dusts in the western North Pacific and analysed for organic carbon (OC), elemental carbon (EC), water-soluble organic carbon (WSOC), water-soluble total nitrogen (WSTN), water-soluble organic nitrogen (WSON) and major ions to better understand the formation and transformation of East Asian aerosols during long-range atmospheric transport. Concentration ranges of these components are; OC: 0.76–$7.1\,\mu g\,m^{-3}$ (av. $1.7 \pm 1.0\,\mu g\,m^{-3}$), EC: 0.07–$0.96\,\mu g\,m^{-3}$ ($0.28 \pm 0.19\,\mu g\,m^{-3}$), WSOC: 0.27–$1.9\,\mu g\,m^{-3}$ ($0.73 \pm 0.38\,\mu g\,m^{-3}$), WSTN: 0.77 to $3.0\,\mu g\,m^{-3}$ ($0.58 \pm 0.46\,\mu g\,m^{-3}$) and WSON: 0.0–$2.2\,\mu g\,m^{-3}$ ($0.12 \pm 0.23\,\mu g\,m^{-3}$). Higher OC concentrations were obtained in active biota seasons; spring (av. $2.4\,\mu g\,m^{-3}$) and summer ($1.8\,\mu g\,m^{-3}$). EC and WSOC concentrations maximized in spring (av. $0.41\,\mu g\,m^{-3}$ and $0.95\,\mu g\,m^{-3}$, respectively) followed by winter (0.70 and $0.90\,\mu g\,m^{-3}$) whereas they became lowest in summer (0.19 and $0.52\,\mu g\,m^{-3}$). In contrast, WSTN concentrations were highest in winter ($0.86\,\mu g\,m^{-3}$) and lowest in summer ($0.37\,\mu g\,m^{-3}$) and autumn ($0.34\,\mu g\,m^{-3}$). Concentrations of WSON are higher in early summer (av. $0.26\,\mu g\,m^{-3}$) due to the emission from marine biota. The high ratios of OC / EC (av. 7.6) and WSOC / OC (44 %) suggest a secondary formation of organic aerosols. Strong correlation between OC and MSA$^-$ (0.81) in spring suggests that springtime aerosols are influenced by additional marine and terrestrial biogenic sources. The positive correlation of Ca^{2+} and TSP in spring ($r = 0.81$) demonstrates a significant contribution of Asian dust whereas high abundances of NO$_3^-$ and nss-SO$_4^{2-}$ in winter suggest an important contribution from anthropogenic sources including biomass burning, vehicular emission and coal combustion. NH$_4$-N/WSTN ratios peaked in winter (0.56), indicating a significant contribution of biomass burning to WSTN in cold season. In contrast, higher NO$_3$-N/WSTN ratio in spring than winter suggests that the atmospheric transport of vehicular emissions maximizes in spring. Correlation analyses of major ions suggest that NH$_4^+$ and Ca^{2+} play major role in the neutralization of acidic aerosols forming NH$_4$HSO$_4$, (NH$_4$)$_2$SO$_4$ and CaSO$_4$.

1 Introduction

Aerosols affect the Earth's radiative forcing directly by scattering and absorbing light and indirectly by acting as cloud condensation nuclei (Buseck and Posfai, 1999). The role of atmospheric aerosols in radiative budget, however, has not been well understood despite many studies (e.g. Ramanathan et al., 2001). Carbonaceous aerosols play major role in climate change and health effect (Folinsbee, 1992). Although EC is minor component in carbonaceous aerosols, it has positive radiative forcing at the top of the atmosphere (TOA) and negative radiative forcing at the surface (Ramanathan et al., 2001). Organic aerosols that contain water-soluble species play an important role in climate forcing (Novakov and Penner, 1993) and cloud condensation nuclei (CCN) activity (Saxena et al., 1995). Large amounts of water-soluble organic compounds including dicarboxylic acids are present in the
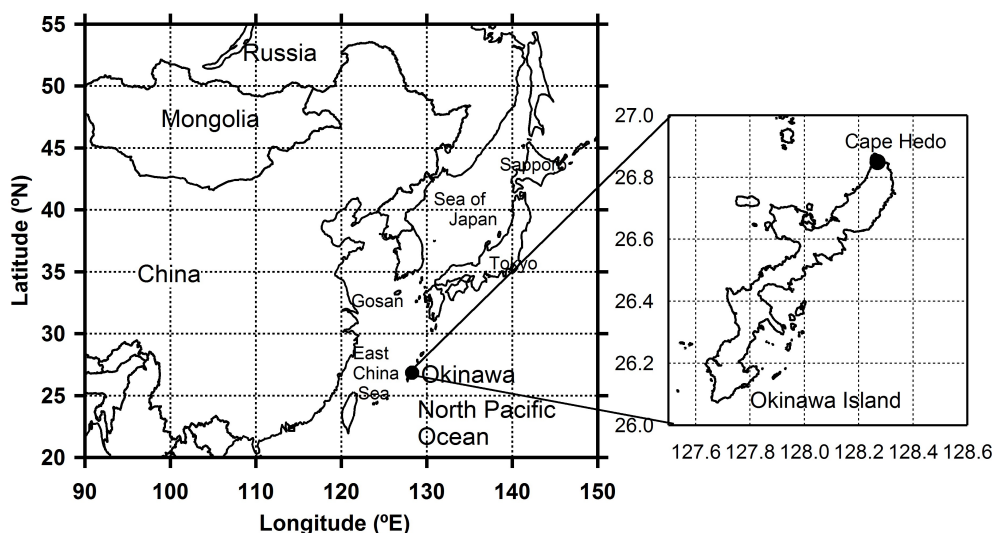

Fig. 1. Map showing the geographical region of Cape Hedo, Okinawa, where sampling was performed.

tropospheric aerosols from urban (Kawamura and Kaplan, 1987), rural (Limbeck et al., 2001), marine (Kawamura et al., 2004), Arctic (Kawamura et al., 1996a, 2010) and Antarctic regions (Kawamura et al., 1996b), supporting that they are important chemical constituents in the atmosphere.

About one fourth of the global anthropogenic carbonaceous aerosols are emitted from China, 70 % of which are originated solely from coal burning (Cooke et al., 1999). Large amounts of low quality coal are used for house heating and cooking purposes (Wang et al., 2006). Light absorbing EC and light scattering OC have been abundantly reported in Chinese aerosols (Ho et al., 2007; Cao et al., 2007), which are subjected to long-range transport over the western North Pacific. Okinawa Island is located in the outflow region of Asian aerosols and on the pathway to the Pacific. Cape Hedo is located on the northern edge of Okinawa and has been used as a supersite of Atmospheric Brown Clouds (ABC) project to study the atmospheric transport of Chinese aerosols and their chemical transformation in East Asia (Takami et al., 2007). In the Asian Pacific region, the East Asian monsoon dominates in winter to spring, whereas the monsoon from the Pacific Ocean dominates in summer to fall (Sato et al., 2009), therefore, continental air masses from East Asian countries including Russia, Mongolia, China, and Korea generally arrive over Okinawa during winter and spring.

In this study, we report one-year observations of OC, EC, WSOC, WSTN and major ions in ambient atmospheric aerosols collected at Cape Hedo, Okinawa. We calculate water-soluble organic nitrogen (WSON) based on the difference between WSTN and inorganic nitrogen (NO_3^- and NH_4^+). We discuss the seasonal changes of these components and transformations of organic aerosol (OA) during the long-range transport of Asian aerosols. Many studies related to the atmospheric chemistry have been conducted at Cape Hedo

(Sato et al., 2009; Wang et al., 2009; Zhang et al., 2003; Jaffe et al., 2005; Verma et al., 2011; Lun et al., 2009; Yamamoto and Kawamura, 2011; Ueda et al., 2011; Arakaki et al., 2006; Handa et al., 2010; Mochida et al., 2010). However, no studies were conducted for a long-term measurement of OC, EC, WSOC, WSTN, WSON and major ions in atmospheric aerosols from Cape Hedo, Okinawa Island.

2 Samples and analytical procedure

2.1 Sampling site and aerosol collection

Using a high-volume air sampler (Kimoto AS-810B) and pre-combusted (450 °C, 4 h) quartz fiber filters (Pallflex 2500QAT, 20×25 cm), total suspended aerosol (TSP) samples ($n = 50$) were collected on weekly basis at Cape Hedo Atmosphere and Aerosol Measurement Station (CHAAMS, 26°9′ N, 128°2′ E) from 2009 October to 2010 October. The sampling period of each sample was 7 days. Figure 1 shows a map of East Asia with the geographical location of Cape Hedo in Okinawa. CHAAMS is located at the northwestern part of Okinawa Island, Japan and it is surrounded by subtropical forest (Yamamoto and Kawamura, 2011) where local anthropogenic emissions are insignificant (Takami et al., 2007). Aerosol filter samples were placed in a preheated glass jar (150 mL) with a Teflon-lined screw cap and stored in darkness at −20 °C until the analysis. Field blanks were also collected at the site. Blank filter was placed in the filter cartridge of sampler without pumping air. After 10 s, field blank filter was recovered from the cartilage. Quartz fiber filters may adsorb organic vapours, causing positive artefacts on OC measurements. However, due to the relatively long sampling period (one week), we consider that the artefacts may be minimal.

2.2 Chemical analysis

Before the analysis, TSP mass was gravimetrically determined at room temperature of 20 °C and 50 % relative humidity. However, the TSP mass may be overestimated due to the water contained in the marine aerosol filters. OC and EC were measured using a Sunset Laboratory carbon analyser following Interagency Monitoring Protected Visual Environments (IMPROVE) thermal/optical evolution protocol (Wang et al., 2005). Presence of carbonate carbon is assumed to be negligible, except for two spring samples, which showed that the pH of the filter extracts were alkaline. A filter disk (1.5 cm^2 punch) was put in quartz boat inside the thermal desorption chamber and stepwise heating was applied in a helium flow at first and then after the initial ramp, helium gas was switched to He/O$_2$. The evolved CO$_2$ during the oxidation at each temperature step was measured with non-dispersive infrared (NDIR) detector system. The transmittance of light (red 660 nm) through the filter punch was used for setting up OC / EC split point and thereby OC correction. The analytical errors in duplicate analysis of the filter sample were less than 8 % for OC and 5 % for EC. OC and EC concentrations reported here are corrected for the field blanks.

WSOC and WSTN were determined using a Shimadzu carbon/nitrogen analyser (TOC-V$_{CSH}$) (Miyazaki et al., 2011). A filter disc (3.14 cm^2) was extracted with organic-free pure water under ultrasonication for 15 minutes. The water extracts were filtrated on a syringe filter (Millex-GV, 0.45 µm, Millipore). Before the analysis, the extracts were acidified with 1.2 M HCl and purged with pure air to remove dissolved inorganic carbon and volatile organics. The analytical error in triplicate analysis of laboratory standards was within 5 % (Miyazaki et al., 2011).

Major cations and anions were measured using an ion chromatograph (761 Compact IC, Metrohm, Switzerland). A sample filter disc (20 mm diameter) was extracted with organic-free pure water (10 mL) under ultrasonication (15 min × 2 times). The extracts were filtrated using a membrane disc filter (Millex-GV, 0.45 µm, Millipore) and injected to IC for measuring major ions. Anions were separated on a SI-90 4E Shodex column (Showa Denko, Tokyo, Japan) using a mixture of 1.8 mM Na$_2$CO$_3$ and 1.7 mM NaHCO$_3$ at a flow rate of 1.2 mL min^{-1} as an eluent and 40 mM H$_2$SO$_4$ for suppressor. For cation measurements, a Metrosep C2-150 (Metrohm) column was used by using a mixture of 4 mM tartaric acid and 1 mM dipicolinic acid as an eluent at a flow rate of 1.0 mL min^{-1}. The injection loop volume was 200 µL. The analytical errors in duplicate analysis of the authentic standards were within 5 %. We determined total 11 ions including methanesulfonate (MSA$^-$). The detection limits for anions and cations were ca. 0.1 ng m^{-3}. The field blanks for Na$^+$ and Ca^{2+} are 0.078 and 0.144 ng L^{-1}, respectively, whereas those for MSA$^-$, Cl$^-$, NO$_3^-$ and SO$_4^{2-}$ were 0.003, 0.01,

0.001 and 0.011 ng L$^-$, respectively. Here, we report the concentrations of all species after the blank correction.

2.3 Estimate of organic matter and secondary organic carbon

Abundances of organic matter (OM) in the atmosphere are generally estimated by multiplying the measured OC concentrations with the conversion factor of 1.6 ± 0.2 for urban and 2.1 ± 0.2 for aged aerosols (Turpin and Lim, 2001). As mentioned above, our sampling site is located in the outflow region of East Asian aerosols and local anthropogenic activities are negligible. During the atmospheric transport, aerosols are subjected to aging processes to result in more oxygenated organic species (Kawamura et al., 2004; Kundu et al., 2010). Thus, it is better to take 2.1 ± 0.2 instead of 1.6 ± 0.2 for the Cape Hedo samples.

The contributions of the primary and secondary organic carbon (SOC) to carbonaceous aerosols are calculated by EC-tracer method. EC is used as a tracer of incomplete combustions generated from primary sources (e.g. Turpin and Huntzicker, 1991). The EC-tracer method assumes the relatively constant OC / EC ratios for given area, season and local meteorology because EC and primary OC (POC) typically have the same sources (Pavuluri et al., 2011). Thus, we can use the minimum OC / EC ratios to estimate the contribution of SOC in the atmospheric aerosol for a specific region of interest (Castro et al., 1999). This method is also applied in several atmospheric researches (Turpin and Huntzicker, 1995; Castro et al., 1999; Pavuluri et al., 2011) although it involves some degree of uncertainty. In this study, the concentrations of SOC and POC were calculated by the following equations

$$POC = EC \times (OC / EC)_{min} + k \quad (1)$$
$$SOC = OC_{meas} - POC, \quad (2)$$

where (OC / EC)$_{min}$ is the observed minimum OC / EC ratio during the sampling period, k is a parameter for non-combustion sources contributing to the POC that is assumed to be negligible, and OC$_{meas}$ is the measured OC concentration. The minimum OC / EC ratios in winter, spring, summer and autumn are 3, 4, 5, and 3, respectively.

2.4 Estimate of sea salt and non-sea salt component

In order to determine whether it is oceanic or continental, sea salt (ss) and non-sea salt (nss) concentrations were calculated using Na$^+$ as a reference element. The mass concentrations of non-sea salt component X (M_{nss-x}) can be estimated as follows (George et al., 2008).

$$M_{nss-x} = M_x - (X/Na)_{sw} \times M_{Na}, \quad (3)$$

where M_x and M_{Na} mean the total mass loading of X and Na, respectively. (X/Na)$_{sw}$ represents the mass ratio of species X to Na in seawater. The ratios of X/Na for SO$_4^{2-}$, K$^+$, Ca^{2+}

and Mg^{2+} are 0.25, 0.037, 0.038 and 0.12, respectively, assuming that sea salt is the only source of water-soluble Na^+ (Berg and Winchester, 1978). By using above equation, the mass concentrations of ss- and nss-SO_4^{2-}, K^+, Ca^{2+}, and Mg^{2+} are calculated.

2.5 Estimate of chlorine loss

Chlorine depletion can be estimated using following formula (Yao and Zhang, 2012).

$$Cl_{loss}(\mu g\,m^{-3}) = 1.798 \cdot [Na^+]_{measured} - [Cl^-]_{measured}$$

$$Cl_{loss}(\%) = [Cl_{loss}]/1.798[Na^+]_{measured} \cdot 100,$$

where $[Na^+]_{measured}$ and $[Cl^-]_{measured}$ represent measured concentrations of Na^+ and Cl^- in $\mu g\,m^{-3}$, respectively. The mass concentration ratio of Cl^- to Na^+ in seawater is 1.798 (George et al., 2008). The following two reactions are associated with the loss process of Cl.

$$HNO_3(g) + NaCl(p) = HCl(g) + NaNO_3(p)$$

$$H_2SO_4(g) + 2NaCl(p) = 2HCl(g) + Na_2SO_4(p).$$
2.6 Backward air mass trajectory analysis

Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT4) model (http://www.arl.noaa.gov/ready/hysplit4.html) was used to find the source regions of air masses at Okinawa during one-year campaign (Draxler and Rolph, 2003). 5-day back trajectory analysis at 500 m above the ground was performed every day using the HYSPLIT model. Figure 2 shows the 5-day air mass trajectories for winter, spring, summer and autumn seasons. In spring and winter, Cape Hedo was strongly influenced by continental air masses (Fig. 2a and 2b). In contrast, in summer, the site was covered with oceanic air masses (Fig. 2c) whereas in autumn it was affected by both oceanic and continental air masses (Fig. 2d). As described previously, the sampling period is 7 days for each sample. Thus, each sample contains mixed air masses from continent and ocean.

## 3 Results and discussion

3.1 Aerosols mass loading

The aerosol mass loading at Okinawa ranged from 19.2 to 286 $\mu g\,m^{-3}$ with an average of 74.3 $\mu g\,m^{-3}$ during one-year observation period. Figure 3 shows the monthly averaged aerosol mass concentrations at Okinawa with error bars denoting the standard deviation. The average mass concentration shows a peak ($109 \pm 69.9\,\mu g\,m^{-3}$) during spring season (March, April and May) and decrease towards the summer ($44 \pm 36\,\mu g\,m^{-3}$). The westerly winds are responsible for such a high peak in spring, by uplifting the mineral dusts from the arid regions in China and Mongolia followed by a transport to the Pacific together with pollutants emitted from Chinese cities. During the Asian dust outflow, crustal elements (calcium, iron, aluminium, barium, etc.) are abundant in dust particles and loess deposits (Nishikawa et al., 2000). A good correlation between Ca^{2+} and TSP ($r = 0.81$) in spring suggests that the spring aerosols are significantly influenced by dust particles from arid regions in China and Mongolia. During spring, Asian dust is the source of Ca^{2+}. Air mass back trajectories also demonstrated that in spring, air masses mostly originated from the arid regions of the Asian continent.

3.2 Seasonal variations of carbonaceous and nitrogenous components

Table 1 gives the concentrations of carbonaceous components with statistical summaries in the TSP samples ($n = 50$) collected from Cape Hedo, Okinawa. Their monthly variations are shown in Fig. 4. The average concentrations of OC, EC, WSOC and WSTN ranged from 0.76 to 7.12 $\mu g\,m^{-3}$ (av. 1.78 $\mu g\,m^{-3}$), 0.07-0.96 $\mu g\,m^{-3}$ (0.28 $\mu g\,m^{-3}$) 0.27-1.9 $\mu g\,m^{-3}$ (0.73 $\mu g\,m^{-3}$) and 0.07-3.02 $\mu g\,m^{-3}$ (0.58 $\mu g\,m^{-3}$), respectively. Seasonally average concentration of OC was found highest in spring (2.36 $\mu g\,m^{-3}$) followed by summer (1.79 $\mu g\,m^{-3}$) and winter (1.53 $\mu g\,m^{-3}$) whereas the lowest concentration was observed in autumn (1.42 $\mu g\,m^{-3}$). Similarly, the highest concentrations of EC and WSOC were found in spring (0.41 $\mu g\,m^{-3}$ and 0.95 $\mu g\,m^{-3}$) followed by winter (0.70 and 0.90 $\mu g\,m^{-3}$). In contrast, the lowest concentrations of EC and WSOC were obtained in summer (0.19 and 0.52 $\mu g\,m^{-3}$).

OC showed higher concentration during winter in Chinese aerosols (Wang et al., 2011; Cao et al., 2003, 2007; Ho et al., 2007) because low quality coals are commonly used for heating and cooking purposes. Very high concentration of OC was reported in winter than spring in urban regions of China (Wang et al., 2011). In contrast, we found higher concentration of OC in spring although most of the air parcels came from China, suggesting the additional contribution to OC from biogenic sources because biogenic emissions are significant in spring season (Pavuluri et al., 2010). The springtime maxima of OC (Fig. 4a) and WSOC (Fig. 4c) suggest that they are formed by extensive photochemical oxidation of various organic precursors emitted from fossil fuel combustion and biomass burning as well as biogenic volatile organic compounds (BVOCs) from terrestrial plants. EC also maximized in spring followed by winter, suggesting significant contributions of EC from China through long-range atmospheric transport by westerly winds. Water-insoluble organic carbon (WIOC = OC − WSOC) showed the highest concentration in spring (1.41 $\mu g\,m^{-3}$) followed by summer (1.27 $\mu g\,m^{-3}$).
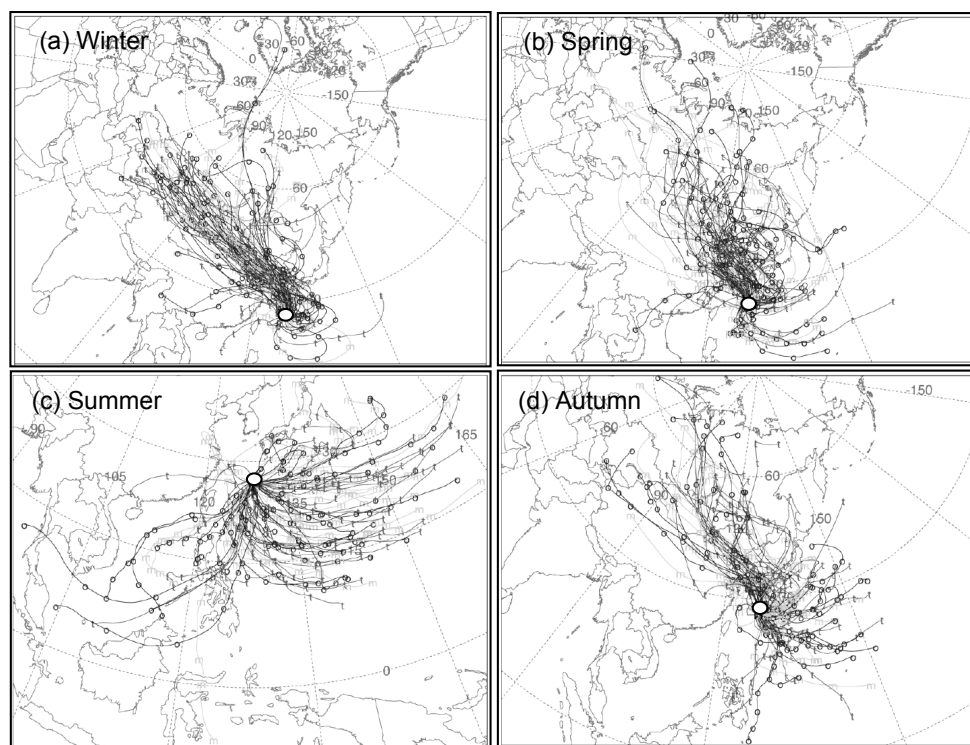

Fig. 2. Five-day backward trajectory analysis for four seasons; **(a)** winter (December, January and February), **(b)** spring (March, April and May), **(c)** summer (June, July and August), and **(d)** autumn (September, October and November). Backward trajectories at 500 m above ground level were drawn with the NOAA HYSPLIT model.

Table 1. Seasonal variations of mass concentrations of different organic components in aerosols from Cape Hedo, Okinawa.

| | Concentration in (μg m^{-3}) | | | | | | | |
| | Winter | | Spring | | Summer | | Autumn | |
Components	Range	AV $\pm$ SD	Range	AV $\pm$ SD	Range	AV $\pm$ SD	Range	AV $\pm$ SD
OC	0.83–2.49	1.53 $\pm$ 0.51	1.04–7.12	2.36 $\pm$ 1.71	0.84–3.01	1.79 $\pm$ 0.56	0.76–2.52	1.42 $\pm$ 0.48
EC	0.14–0.59	0.70 $\pm$ 0.51	0.19–0.96	0.41 $\pm$ 0.24	0.07–0.54	0.19 $\pm$ 0.14	0.09–0.38	0.20 $\pm$ 0.09
WSOC	0.45–1.37	0.90 $\pm$ 0.29	0.53–1.88	0.95 $\pm$ 0.40	0.27–1.90	0.52 $\pm$ 0.42	0.29–0.70	0.55 $\pm$ 0.18
WIOC	0.08–1.12	0.63 $\pm$ 0.25	0.51–5.24	1.41 $\pm$ 1.34	0.57-2.29	1.27 $\pm$ 0.41	0.37–1.84	0.89 $\pm$ 0.51
OM	1.66–4.98	3.05 $\pm$ 1.02	2.07–14.2	4.72 $\pm$ 3.42	1.68–6.02	3.59 $\pm$ 1.12	1.52-5.04	2.85 $\pm$ 0.95
WSOM	0.90–2.74	1.80 $\pm$ 0.58	1.06–3.76	1.91 $\pm$ 0.81	0.54-3.80	1.05 $\pm$ 0.85	0.57-1.81	1.12 $\pm$ 0.41
WIOM	0.16–2.24	1.26 $\pm$ 0.51	1.02-10.4	2.82 $\pm$ 2.69	1.14–4.59	2.54 $\pm$ 0.82	0.75–3.69	1.73 $\pm$ 0.81
POC	0.63–1.17	1.08 $\pm$ 0.40	0.56-2.12	1.60 $\pm$ 0.98	0.35–2.71	0.93 $\pm$ 0.68	0.25–2.80	0.59 $\pm$ 0.28
SOC	0.17–0.71	0.44 $\pm$ 0.13	0.12–3.60	0.74 $\pm$ 0.93	0.30–1.36	0.86 $\pm$ 0.39	0.08–2.60	0.84 $\pm$ 0.57

EC and WSOC show similar seasonal variations (Fig. 4b, c), suggesting that they are formed from similar sources. The average highest concentration of primary organic carbon (POC) is found in spring followed by winter whereas the higher concentration of secondary organic carbon (SOC) was found in spring and summer, as shown in Fig. 4e and 4f. The highest concentration of SOC was observed in March with an increase toward July. The average highest concentration of SOC in summer may be caused by photochemical oxidation of organic precursors under a strong solar radiation as

well as emission of marine volatile organic carbon (Shaw et al., 2010). The higher wind speed during spring may be responsible for higher POC concentration.

WSTN showed higher concentrations during winter (0.86 μg m^{-3}) followed by spring (0.77 μg m^{-3}) although the concentrations during spring months are almost constant whereas they showed lower concentrations during summer and autumn (0.37 and 0.34 μg m^{-3}). The higher concentration of WSTN during winter suggests that WSTN is abundantly present in polluted air. Meanwhile, concentrations
Fig. 3. Average monthly variation of aerosol mass loading in ambient aerosols collected in Cape Hedo, Okinawa.

of water-soluble organic nitrogen (WSON = WSTN − NO$_3$-N–NH$_4$-N) ranged from 0 to 2.2 μg m^{-3} (av. 0.11 μg m^{-3}). WSON comprised on average 18.9 % of WSTN. Marine organisms are probably the main sources of WSON. Terrestrial and marine organisms emit nitrogenous components, which contain certain amount of WSON (Wang et al., 2013a). Marine bacteria and degraded proteins are the sources of WSON (Wedyan and Preston, 2008). Marine biota also can emit amino acids, urea and proteins. WSON is emitted to the atmosphere by bubble bursting process in the ocean surface (Cape et al., 2011). We found the highest concentration of WSON in summer (av. 0.21 μg m^{-3}) followed by spring (0.13) and autumn (0.07) and lowest concentration in winter (0.06). The summertime maximum of WSON suggests that they are emitted from marine biota.

We found that the contribution of OM to TSP is on average 6.27 ± 3.7 %. The highest average contribution of OM to TSP was found in summer (9.5 %) followed by autumn (5.31 %) and spring (4.85 %), and the lowest (4.48 %) in winter (Fig. 5). The contribution of WSOM to TSP was found highest in winter (2.71 %) followed by summer (2.60 %). In contrast, the contribution of WIOM (water insoluble organic matter) to TSP became highest in summer (6.9 %), suggesting more emission of WIOM in summer probably from biological sources (Miyazaki et al., 2011). The average contribution of EC to TSP was found highest in winter (0.54 %), and lowest in summer (0.42 %). In this study, a strong correlation was found between OC and EC in winter ($r = 0.93$) and spring (0.81), suggesting that they are formed from similar sources (Turpin et al., 1991). However, such a strong relation was not found in summer (0.44) (Fig. 6), indicating that OC has at least two independent sources that distort the correlation. During winter and spring, our sampling site is significantly influenced by the outflow of polluted air masses from East Asian countries, thus we obtained strong correlation between OC and EC. However, in summer, anthropogenic contributions are negligible in Cape Hedo, hence the correlation between OC and EC is rather weak.

3.3 Seasonal variations of OC / EC and WSOC / OC ratios

OC / EC ratio has been used to study the emission and transformation characteristics of carbonaceous aerosols (Cao et al., 2003). The OC / EC ratios exceeding 2.0 have been considered to indicate the contribution of secondary organic aerosols (Cao et al., 2003). In our study, OC / EC ratios ranged from 3.5 to 21 with average of 7.6 ± 4.7. The season-averaged OC / EC ratios are 4.4 (winter), 5.7 (spring), 12.5 (summer) and 7.7 (autumn). Most of the world's urban OC / EC ratios range from 1 to 4 (Turpin et al., 1991). A ratio of 4.0 is also assumed for emissions from fossil fuel combustion (Koch, 2001). The average ratio is still higher in spring than winter although EC showed higher concentration in spring. The OC / EC ratios obtained in this study, except for summer samples, are comparable to those from Mongolia and Chinese cities (Jung et al., 2010; Cao et al., 2007). Compared to the world's urban OC / EC ratios, our summer OC / EC ratio (12.5) is extremely high, suggesting an extra

source of OC from the ocean and/or secondary OC formation via the oxidation of BVOCs in summer. Tambunan et al. (2006) showed that the emissions of isoprene and other BVOCs maximize in Okinawa during summer. Generally, their emissions are higher in summer (Kim et al., 2005).

Figure 7a shows the monthly variation of OC / EC ratios. In November we obtained relatively high OC / EC ratio. This may be caused by long-range atmospheric transport of biomass burning plumes from Southeast Asia because biomass burning is very common in the region in autumn (Wang et al., 2013b) and the air masses mostly came from Southeast Asia including Philippines (Fig. 2d). OC / EC ratios from biomass burning give higher values of 5 to 8 (Andreae and Merlet, 2001). We found a strong correlation ($r = 0.87$) between OC and biomass burning tracer (nss-K^+) in autumn, indicating a significant influence of biomass burning on organic aerosols. The enhanced OC / EC ratios were found in summer with a peak in July. The summer maximum may be caused by the secondary formation of OC via the oxidation of various VOCs during long-range atmospheric
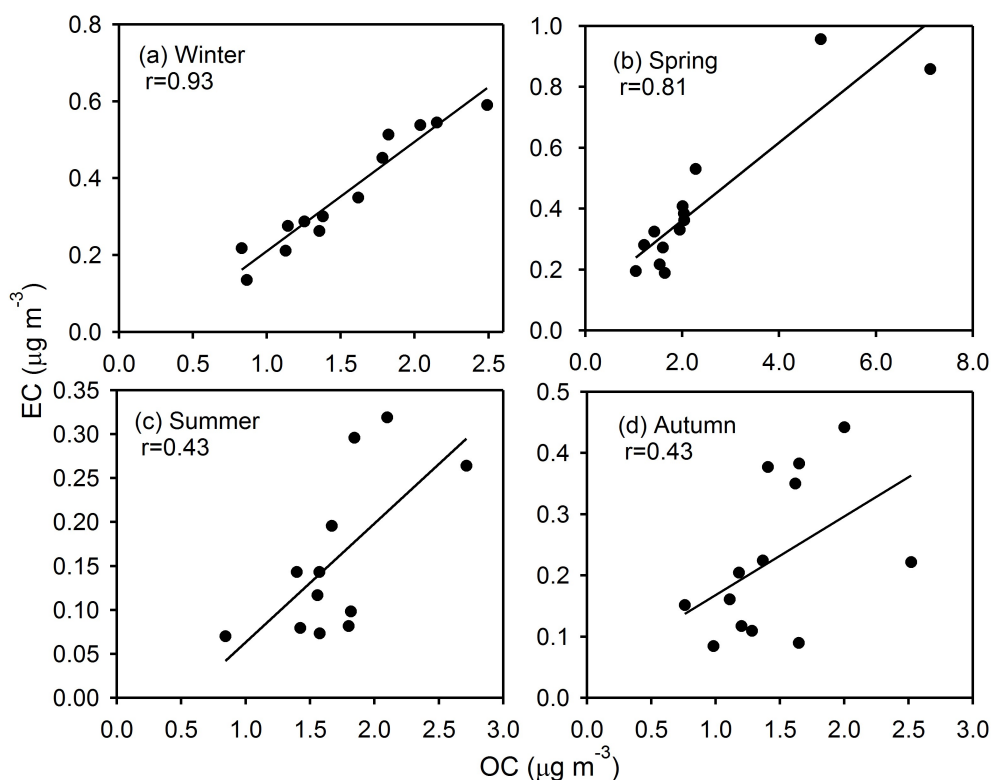

Fig. 6. Correlation analysis between elemental carbon (EC) and organic carbon (OC) in ambient aerosol samples collected from Cape Hedo Okinawa.

transport. Cao et al. (2005) showed that aerosols from residential coal combustion contain high OC / EC ratio (12). The average OC / EC ratios for winter (4.4) and spring (5.7) samples are comparable with the value (3.8) reported in 14 Chinese cities (Cao et al., 2007), indicating that our sampling site is significantly influenced by anthropogenic aerosols from China.

WSOC to OC ratio is useful to discuss the potential sources (Jung et al., 2010) and to understand photochemical oxidation (Miyazaki et al., 2010b) and extent of gas to particle formation of secondary WSOC (Hagler et al., 2007). Figure 7b shows the monthly averaged variation of WSOC / OC. The annual average ratio in Cape Hedo was $43 \pm 15\%$ (range, 15 to 90 %). This value is lower than the ratios reported in Mongolian aerosols (31–97 %, av. 53 %) (Jung et al., 2010), Christchurch, New Zealand (48 %, Wang et al., 2005) but similar to those from Sapporo, Japan (44 %, Aggarwal and Kawamura, 2008) and from 14 Chinese cities (summer 48 % and winter 40 %, Ho et al., 2007). However, lower WSOC / OC ratios were reported from Gosan, Korea (30 %) during the ABC campaign (Miyazaki et al., 2007), from New Delhi, India (25 %) in nighttime (Miyazaki et al., 2009), and from Tokyo (summer 20 % and winter 35 %, Miyazaki et al., 2006). Mayol-Bracero et al. (2002) reported higher WSOC / OC ratios (45–75 %) in biomass burning aerosols over Amazonia. The smouldering biomass

Note: BDL means Below Detection Limit (0.001 $\mu g\,m^{-3}$).

combustion produces WSOC abundantly (Andreae et al., 1996). The higher WSOC / OC ratio in winter (Fig. 7b) suggests that significant fractions of organic aerosols were derived from biomass burning together with atmospheric oxidation of fossil fuel combustion products.

Kawamura et al. (2010) reported an increase of WSOC/TC ratios in the Arctic aerosols after polar sunrise due to extensive photochemical oxidation of organic precursors. The enhanced WSOC / OC ratios (av. 81 %) were also reported for summit Greenland aerosol (Hagler et al., 2007). We found highest WSOC / OC ratios in winter (60 %) followed by spring (45 %) and autumn (41 %). The lowest WSOC / OC ratio was observed in summer (28 %). The low ratio in summer may be caused by the sea-to-air emissions of water-insoluble organic compounds that are produced by marine phytoplankton, because the summertime air masses are derived from the oceanic region (Fig. 2c). The average summertime WSOC / OC ratio from Cape Hedo aerosols (28 %) is slightly lower than that from Delhi aerosols (36 %). In summer, Delhi aerosols were also influenced by marine sources (Aggarwal et al., 2013). Miyazaki et al. (2010b) reported high abundance of WIOC in the western North Pacific during summer. The highest ratios in winter (60 %) may be due to the enhanced oxidation of primary organic compounds during long-range atmospheric transport and/or gas-to-particle conversion of anthropogenic semi-volatile polar compounds (Kawamura et al., 2010).

The previous studies of East Asian aerosols often showed wintertime maxima of OC. However, it is not the case in our samples from Cape Hedo. Table 3 compares the concentration of OC and EC together with OC / EC ratios in East Asia. The annual average concentration of OC in Cape Hedo (1.78 $\mu g\,m^{-3}$) is significantly less than those reported in Mongolia during winter (Jung et al., 2010), Chinese cities (Cao et al., 2007), Pearl Delta region, China (Cao et al., 2003), Kaohsiung, Taiwan (Lin and Tai, 2001) and Seoul, Korea (Park et al., 2002), and is also lower than that of Jeju Island (Lee et al., 2001) where Asian outflow is important. Based on these comparisons, we can insist that concentrations of OC decrease during long-range atmospheric transport via atmospheric dilution and/or dry and wet scavenging. The major sources of carbonaceous components include industrial and vehicular emissions, fossil fuel combustions and biomass burnings in East Asia (Wang et al., 2006).

3.4 Seasonal variations of inorganic species

The statistical summaries of water-soluble ionic species in the marine aerosol samples from Okinawa are given in Table 2. Their seasonal variations of cations and anions are shown in Fig. 8. The dominant cation in our samples was Na^+ followed by Mg^{2+} and Ca^{2+}. The annual average concentrations of Na^+, Mg^{2+} and Ca^{2+} are 5.78, 0.71 and 0.66 $\mu g\,m^{-3}$, respectively, whose relative contributions to total aerosol mass are 9.3, 1.1 and 0.8 %, respectively. The
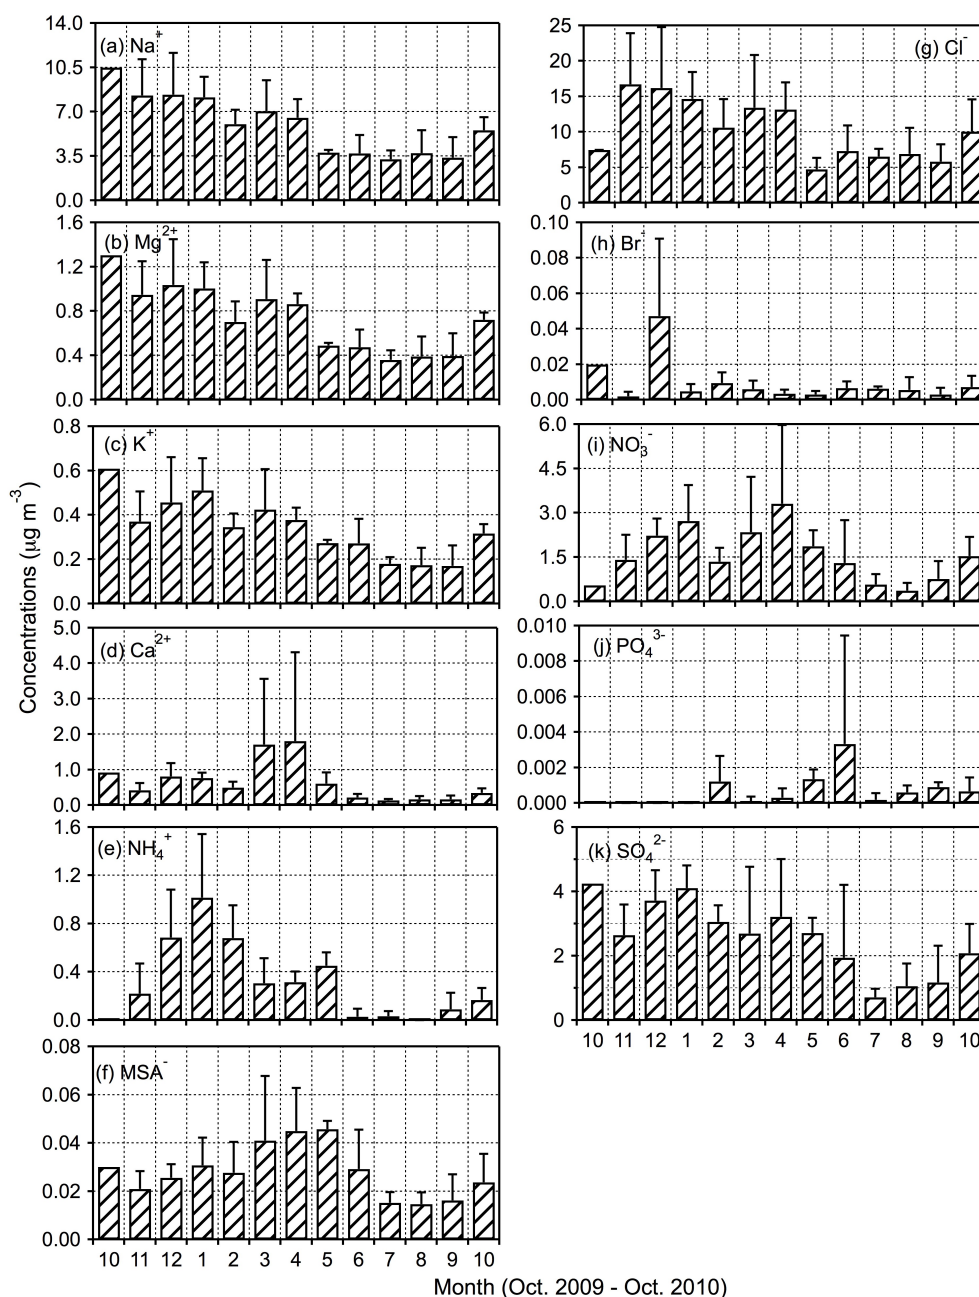

**Fig. 8.** Monthly average variations in concentrations of major ions **(a)** Na^+, **(b)** Mg^{2+}, **(c)** K^+, **(d)** Ca^{2+}, **(e)** NH_4^+, **(f)** MSA^-, **(g)** Cl^-, **(h)** Br^-, **(i)** NO_3^-, **(j)** PO_4^{3-}, and **(k)** SO_4^{2-} in the ambient aerosols collected from Cape Hedo, Okinawa.

dominant anion was Cl^- followed by SO_4^{2-} and NO_3^-. Their annual average concentrations are 10.8, 2.4 and 1.6 µg m^{-3}, respectively, whose relative contributions to total aerosol mass were 17.1, 3.7 and 2.5 %, respectively. Similarly, the contributions of Na^+ and Cl^- to total ions were on average 26.2 % and 47 %, respectively. Average concentration of Cl^- is 6 times higher than that of OC, suggesting that inorganic loading is very important throughout the year. MSA^-, a tracer of marine biogenic sources, showed high concen-
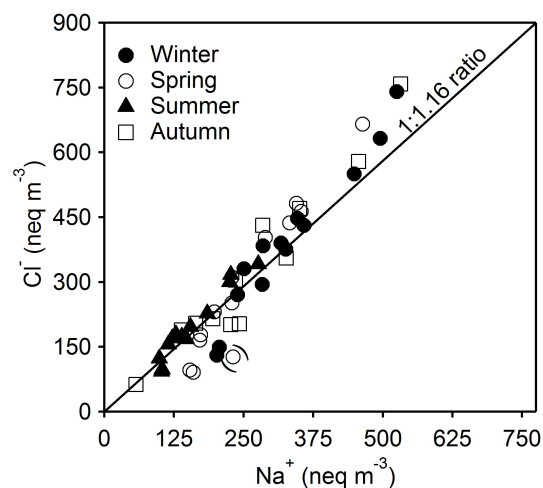

tration in spring, suggesting the emissions from biogenic marine sources. During the long-range atmospheric transport, East Asian aerosols travelled over the marine regions (the East China Sea, Sea of Japan and Pacific Ocean) and resided over the marine atmosphere for 1 to 2 days. During the travelling, the aerosol from East Asia is mixed with marine aerosols emitted from the ocean, which can be supported by individual backward trajectory. The summertime concentration of MSA^- in Cape Hedo is comparable with

those in the western North Pacific during summer (Miyazaki et al., 2010a). Similarly, nss-K$^+$, a tracer of biomass burning, showed a good correlation with OC in winter (0.72) and spring (0.65). The stronger correlation in winter suggests that biomass burning significantly contributes in winter than spring. Most cations and anions showed the highest concentrations in winter months and the lowest in summer (Fig. 8).

The relative abundances of NO$_3^-$, SO$_4^{2-}$, NH$_4^+$ in TSP showed a maximum in winter. These results suggest that contributions from fossil fuel combustion, industrial emission, and biomass burning are significant (Kundu et al., 2010) as well as animal excreta for NH$_3$ (Pavuluri et al., 2011). In contrast, relative abundances of Ca^{2+} in TSP maximized in spring (Fig. 8d), suggesting a significant influence from

crustal dust during spring. Concentrations of Ca^{2+} (a tracer of crustal material) also maximized in spring.

3.4.1 Ion balance and correlations among major ions

Ion balance calculation is used to evaluate the ion deficit between cations and anions in aerosols (Pavuluri et al., 2011). The following equations are used to derive the charge balance between cations and anions.

Cation equivalents $= [Na^+]/23 + [NH_4^+]/18 + [K^+]/39 + 2 \times [Mg^{2+}]/24 + 2 \times [Ca^{2+}]/40$.

Anion equivalents $= 2 \times [SO_4^{2-}]/96 + [NO_3^-]/62.04 + [Cl^-]/35.5 + [Br^-]/79.9 + [MSA^-]/95.1 + 3 \times [PO_4^{3-}]/94.8$.

Average equivalent ratios of total cations (Na^+, NH_4^+, K^+, Mg^{2+}, and Ca^{2+}) to total anions (SO_4^{2-}, NO_3^-, Cl^-, Br^-, MSA^- and PO_4^{3-}) were 0.96 with standard deviation of 0.14 ($n = 50$) as shown in Fig. 9. The slope (0.87) of less than 1 indicates that almost all of the ions had been quantified, although CO_3^{2-}, HCO_3^-, H^+ and organic anions were not determined.

Because the concentration of the ions emitted from the same source or similar reaction pathway should show a good correlation, correlation analyses among the ions would provide important information for their sources. Tables 4, 5, and 6 show the results of correlation analyses of major ions for winter, spring, and summer, respectively. Throughout the year, we found strong correlations among Na^+, sea salt (ss)-K^+, ss-Ca^{2+}, ss-Mg^{2+}, ss-SO_4^{2-} and Cl^-, indicating that these ions are derived from the sea spray.

In winter, NO_3^-, a tracer of anthropogenic source, strongly correlates with NH_4^+, nss-K^+, and well correlates with nss-Mg^{2+} (Table 4), suggesting that they are derived from anthropogenic sources in the Asian Continent. In spring, we did not find any significant correlation between Na^+ and NO_3^- (Table 5). However, nss-Ca^{2+}, a tracer of crustal dust, was found to well correlate with nss-K^+ and nss-Mg^{2+}, indicating that they are derived from similar sources or reaction pathways. There is no correlation between nss-Ca^{2+} and Na^+ in spring (Table 5). In summer, NO_3^- showed a strong correlation with nss-Mg^{2+} and nss-SO_4^{2-} (Table 6), suggesting that they are formed from similar sources and/or reaction pathways. Both NO_3^- and nss-SO_4^{2-} are produced by photochemical reactions in the atmosphere (Pavuluri et al., 2011). It should be noted that ss-SO_4^{2-} showed good correlations with NH_4^+ and NO_3^- as well as other anthropogenic tracers (nss-K^+, nss-Mg^{2+}) during winter and spring (Tables 4 and 5). NH_3 and HNO_3 probably react with sea salt in the marine atmosphere.

3.4.2 Sea salt and non-sea salt ions

Sea salt is the major component in the marine and coastal aerosols (George et al., 2008; Prospero, 2002). Na^+ is used as a tracer to evaluate the contributions of sea salt to aerosols.

The equivalent ratio of Cl^- to Na^+ is 1.16 in seawater. We estimated equivalent ratios of Cl^-/Na^+ in each samples and compared with seawater. Figure 10 presents scatter plots of Na^+ and Cl^- concentration for different seasons. Throughout the year, only few data points are found to locate below the sea water line, indicating that the loss of Cl was insignificant except for spring samples. Chlorine loss has been observed in many coastal regions and open oceans (Meinert and Winchester, 1977; George et al., 2008; Yao and Zhang, 2012). In some spring samples, estimated chlorine loss was up to 50 %, indicating that vigorous reaction occurs between gaseous HNO_3 and H_2SO_4, and NaCl to emit gaseous HCl (McInnes et al., 1994) in spring.

Ions such as SO_4^{2-}, K^+, Ca^{2+}, and Mg^{2+} have multiple sources, i.e. oceanic and continental. Additionally, SO_4^{2-} has another oceanic, but nss-source generated by the oxidation of dimethyl sulphide (DMS) that is emitted from the phytoplankton in the sea surface (George et al., 2008; Savoie et al., 1994). Figure 11 shows the monthly variation of ss- and nss-species. ss-Mg^{2+} and K^+ dominate over the nss forms. Interestingly, nss-Ca^{2+} dominated over the ss-Ca^{2+} until May with maxima in March and April while after June it was replaced by the ss-Ca^{2+} (Fig. 11b). Major fraction of Ca^{2+} should be derived from Asian dusts in winter and spring (Kawamura et al., 2004). The percentage of nss-Ca^{2+} to total Ca^{2+} was found highest in winter (62 %) to spring (71.5 %) and decreases towards summer (31.1 %). In spring, the air masses uplift the crustal dust in East Asia and transport over the sampling site. We found strong correlation between nss-Ca^{2+} and TSP ($r = 0.81$) in spring, suggesting that crustal dust from East Asia is the main source of TSP. Similar strong correlation was found between nss-Ca^{2+} and TSP in Gosan site, Jeju Island (Kawamura et al., 2004). However, for the rest of the year, we did not find any good correlation between nss-Ca^{2+} and TSP.

Similarly, the contribution of nss-K^+ to total K^+ was found highest in winter (40.6 %) to spring (46.2 %) with a decrease toward summer (37.1 %). K^+ is a tracer of biomass burning (Kundu et al., 2010) whereas EC is a tracer of incomplete combustions of fossil fuel and biomass burning. We found a strong relation between nss-K^+ and EC ($r = 0.80$) (Fig. 12), indicating that the major fraction of EC is formed by biomass burning. The contribution of nss-Mg^{2+} to total Mg^{2+} increased in winter (30.9 %) to spring (35.8 %) and decreased in summer (27.4 %). Because Mg is also found in the crustal dust (Wang et al., 2010), this study again indicates that our sampling site is strongly influenced by Asian dust in spring. Although all the air masses come from the ocean in summer, the loading of sea salt components maximized in winter and spring and became lowest in summer. In winter and spring when westerlies became strong, continental air masses that stayed over the ocean for few days were mixed with marine aerosols according to the backward trajectory analysis.

3.4.3 Anthropogenic aerosols and ionic composition

nss-SO_4^{2-} in the atmosphere is derived from many sources. It can originate from mineral dusts from the desert/arid region, and combustion of fossil fuels. We found the highest concentration of nss-SO_4^{2-} in winter (av. $1.74\,\mu g\,m^{-3}$) followed by spring ($1.38\,\mu g\,m^{-3}$) and the lowest value in summer ($0.51\,\mu g\,m^{-3}$). The higher nss-SO_4^{2-} concentration in winter and spring suggest that the air quality of Cape Hedo is strongly influenced by fossil fuel combustions and industrial emissions in East Asia via a long-range atmospheric transport. However, we also suspect a possible contribution of shipping emissions of nss-SO_4^{2-} in the East China Sea to the Cape Hedo site during winter and spring. NO_3^- is a tracer of anthropogenic activities and is derived from coal combustions, biomass burning and vehicular emissions (Kundu et al., 2010). We found a positive correlation between NO_3^- and

biomass burning tracer (nss-K^+) ($r = 0.65$) in winter, suggesting that NO_3^- is associated with biomass burning.

To better understand the sources of nitrogenous components, we calculated NH_4-N/WSTN and NO_3-N/WSTN ratios. We found that NH_4-N/WSTN ratios maximized in winter (0.56) followed by spring (0.42), suggesting that biomass burning is important sources of WSTN in winter. Similarly, NO_3-N/WSTN showed higher ratios in spring (0.51) followed by winter (0.44) and autumn (0.18). Lowest values of NH_4-N/WSTN (0.07) and NO_3-N/WSTN (0.11) were obtained in summer due to less chance for the continental outflow of polluted air masses.

### 3.4.4 Neutralization factor and ionic composition

The acid neutralization capacity of desired cation is estimated by neutralization factor (NF). NO_3^- and SO_4^{2-}, which are formed by secondary oxidation of NO, NO_2 and SO_2, are major acid-producing anions, whereas Ca^{2+}, Mg^{2+}, NH_4^+

Table 6. Correlation coefficients (r) of major ions in summer aerosols from Cape Hedo, Okinawa.

Fig. 12. Correlation analysis between nss-K and EC in ambient aerosols collected from Cape Hedo, Okinawa.

and K^+ are the cations that neutralize acids. The role of Cl^- in acid production is negligible because Cl^- mainly comes from the ocean as sea salt. We calculated NF and using following formula (Keene et al., 1986).

$$NF(Ca^{2+}) = [nss - Ca^{2+}]/([NO_3^-] + [nss - SO_4^{2-}])$$

$$NF(Mg^{2+}) = [nss - Mg^{2+}]/([NO_3^-] + [nss - SO_4^{2-}])$$

$$NF(K^+) = [nss - K^+]/([NO_3^-] + [nss - SO_4^{2-}])$$

$$NF(NH_4^+) = [NH_4^+]/([NO_3^-] + [nss - SO_4^{2-}])$$

We found that NH_4^+ plays a major role in the neutralization of acidic species. The order of NF is $NH_4^+ > Ca^{2+} > K^+ > Mg^{2+}$. The NF of NH_4^+ and Ca^{2+} were found highest in winter followed by spring, suggesting that all the acidic species were neutralized with $CaCO_3$, $MgCO_3$ and NH_4^+. Ca^{2+} and

SO_4^{2-} show positive correlation ($r = 0.77$), suggesting that these ions mainly exist as $CaSO_4$. The mean Ca^{2+} to SO_4^{2-} mass ratio in our samples is 0.53, being similar to the ionic mass ratio of 0.41 in $CaSO_4$. NH_4^+ and SO_4^{2-} showed a good correlation ($r = 0.87$) with the mean NH_4^+ to SO_4^{2-} ratio of 0.2, which lies in between the NH_4^+ to SO_4^{2-} mass ratios (0.37) and NH_4^+ to HSO_4^- mass ratio (0.18). This result indicates that NH_4^+ and SO_4^{2-} exist in the form of $(NH_4)_2SO_4$ or NH_4HSO_4 and/or the combination of the two forms. Among these forms, the dominant composition may be NH_4HSO_4 because the measured mass ratios (0.2) is closer to the mass ratio of NH_4HSO_4 rather than that of $(NH_4)_2SO_4$.

4   Summary and conclusions

We conducted one-year observation of chemical compositions in aerosol (TSP) samples collected in Okinawa Island, which is located in an outflow region of Asian dusts. The highest aerosol mass loading and highest concentration of nss-Ca^{2+} in spring are caused by strong westerly winds, which uplift the mineral particles from the arid regions in China and Mongolia and then transport over the Pacific.

In contrast to East Asia (wintertime maximum), we found higher concentration of OC in spring (av. $2.36 \, \mu g \, m^{-3}$) than winter (av. $1.53 \, \mu g \, m^{-3}$). Higher concentration of OC was obtained during active biota seasons; spring and summer ($1.79 \, \mu g \, m^{-3}$). We also determined WSTN and WSON. Higher concentrations of WSTN were found in winter and higher WSON concentrations were found in summer, suggesting more emissions of water-soluble organic nitrogen from the ocean.

Springtime maxima of OC / EC ratios, MSA^- and correlation coefficients of OC and EC ($r = 0.81$), and MSA^- (0.81) showed an importance of terrestrial and marine biogenic sources as well as anthropogenic sources in spring although the contribution from biogenic source is less significant. Similarly, moderate positive correlation between OC and nss-K^+ was found in both winter ($r = 0.72$) and spring (0.65), suggesting that biomass burning contribution is higher in winter season followed by spring. We found an extremely higher OC / EC ratio and strong correlation between OC and MSA^- (0.71) in summer, further suggesting a strong biogenic emission of OC coupled with photochemical formation of SOC in hot season. The highest SOC concentration in July suggests the oxidation of organic compounds under strong solar radiation. Very high WSOC / OC ratios (0.6) found in winter suggest an important contribution of biomass burning products from the Asian Continent as well as the active oxidation of anthropogenic primary organic compounds emitted from East Asian countries even in cold season during long-range atmospheric transport, followed by the subsequent gas-to-particle conversion.

The high concentrations of NO_3^- and SO_4^{2-}, and enhanced NH_4-N/WSTN ratio in winter suggest that Cape Hedo is strongly influenced by vehicular emission, biomass burning, industrial emission and coal combustion in East Asia via a long-range atmospheric transport. We found a strong correlation between the biomass burning tracer (nss-K^-) and EC ($r = 0.80$), suggesting an important contribution of incomplete combustion of biomass to EC in the Asian outflow region.
