Abstract. Many ecosystem models have been developed to study the ocean’s biogeochemical properties, but most of these models use simple formulations to describe light penetration and spectral quality. Here, an optical model is coupled with a previously published ecosystem model that explicitly represents two phytoplankton (picoplankton and diatoms) and two zooplankton functional groups, as well as multiple nutrients and detritus. Surface ocean color fields and subsurface light fields are calculated by coupling the ecosystem model with an optical model that relates biogeochemical standing stocks with inherent optical properties (absorption, scattering); this provides input to a commercially available radiative transfer model (Ecolight). We apply this bio-optical model to the equatorial Pacific upwelling region, and find the model to be capable of reproducing many measured optical properties and key biogeochemical processes in this region. Our model results suggest that non-algal particles largely contribute to the total scattering or attenuation (>50% at 660 nm) but have a much smaller contribution to particulate absorption (<20% at 440 nm), while picoplankton dominate the total phytoplankton absorption (>95% at 440 nm). These results are consistent with the field observations. In order to achieve such good agreement between data and model results, however, key model parameters, for which no field data are available, have to be constrained. Sensitivity analysis of the model results to optical parameters reveals a significant role played by colored dissolved organic matter through its influence on the quantity and quality of the ambient light. Coupling explicit optics to an ecosystem model provides advantages in generating: (1) a more accurate subsurface light-field, which is important for light sensitive biogeochemical processes such as photosynthesis and photo-oxidation, (2) additional constraints on model parameters that help to reduce uncertainties in ecosystem model simulations, and (3) model output which is comparable to basic remotely-sensed properties. In addition, the coupling of biogeochemical models and optics paves the road for future assimilation of ocean color and in-situ measured optical properties into the models.

1 Introduction

Marine ecosystem models have increased their relevance by incorporating greatly enhanced spatial resolution and more sophisticated representations of functional groups (e.g., Rothstein et al., 2006). The models vary from the simplest nutrient/phytoplankton/zooplankton/detritus (NPZD) models (e.g., Riley et al., 1949; Denman and Peña, 2002; Schar tau and Oschlies, 2003) to complex models with twenty or more components including different types of plankton, nutrients, and a microbial loop (e.g., Bissett et al., 1999; Moore et al., 2002; Gregg et al., 2003; Lancelot et al., 2005) accompanied with an increase in the number of specified parameters (e.g., Denman, 2003; Friedrichs et al., 2007).

Progress in ocean color remote sensing technology and inversion algorithms has provided ways to assess standing stocks of phytoplankton pigments and carbon (Behrenfeld et al., 2005), particulate organic carbon (POC, Stramski et al., 1999), and colored dissolved organic matter (CDOM, Siegel et al., 2002) through their unique scattering and/or absorption signatures. Global net oceanic primary productivity (carbon fixation) has been estimated with satellite data, based on the derived surface chlorophyll concentration (e.g., Behrenfeld and Falkowski, 1997) and more recently from remote estimation of both phytoplankton carbon and chlorophyll (Behrenfeld et al., 2005). Many of these advances are based on semi-empirical algorithms linking ocean color to the optical properties of the underlying constituents (IOCCG, 2006).

Given the ability to measure optical properties from small, robust, and high-frequency sensors in-situ and on a variety of platforms (e.g., Rudnick and Perry, 2003), a large body of
work has been assembled linking biogeochemical variables to optical properties (e.g., Dickey et al., 2006).

Considering this progress in observational capabilities, if we are to compare models to measurements and/or assimilate measurements into models, it is imperative to contemplate modeling not only the biogeochemical but also the inherent optical properties (IOP) such as absorption and backscattering as state variables, and to directly compare model results to estimates from remotely observed or in-situ measured quantities. Conversion of biogeochemical properties to optical parameters is also needed to realistically model the underwater light field, which is used as an input to model processes such as photosynthesis and photochemistry. The optical consequences of seawater constituents, including dissolved materials, phytoplankton, and non-algal particles (NAP), need to be included in ecosystem models, and the interaction of light with these materials needs to be computed to obtain realistic depth- and wavelength-resolved light fields. However, with very few exceptions (e.g., Bissett et al., 1999), most ecosystem models do not include the physics and bio-optics associated with the underwater light field. In addition, Rothstein et al. (2006) have specifically recommended the development of ecosystem models which includes optics.

In this study, we develop a multi-nutrient phytoplankton, zooplankton, and detritus ecosystem model with associated wavelength-resolved optical properties. We choose to simulate the equatorial Pacific where data from several programs are available (e.g. Murray et al., 1995; Barber et al., 1996; Dupouy et al., 2003; Gardner et al., 2003; Simeon et al., 2003). We will present in this paper that by adding optical properties in the ecosystem model, the model improves in: (1) having more data to compare model output on model formulation and choice of parameter values, and (2) simulation realism for key biogeochemical processes. Model sensitivity studies to the values of optical parameters will demonstrate the crucial role CDOM plays in phytoplankton dynamics, nutrient cycling, and the light field.

2 Model description and experimental design

The bio-optical model constructed in this study consists of four individual models: a physical-ecosystem model (simulating the dynamics of different ecosystem components in time and space), a photo-acclimation model (specifying the chlorophyll to carbon ratio of phytoplankton), an optical model (converting ecosystem state variables into inherent optical properties), and a radiative transfer model (calculating the underwater light field and the ocean color) (Fig. 1). For ease of comparison with data, we demonstrate area-averaged one dimensional (vertical) and time-averaged results. The model, however, is formulated and designed to be used in 4 dimensions.

2.1 Physical-ecosystem model and photo-acclimation model

The physical-ecosystem model used in this study is based on the Carbon, Silicon, Nitrogen Ecosystem (CoSINE) model (Chai et al., 2002), which was originally developed to simulate biogeochemical properties in the equatorial Pacific upwelling region. The ecosystem model explicitly represents two phytoplankton (picoplankton P1 (mmol N m$^{-3}$) and diatoms P2 (mmol N m$^{-3}$)) and two zooplankton functional groups (microzooplankton Z1 (mmol N m$^{-3}$) and mesozooplankton Z2 (mmol N m$^{-3}$)), as well as multiple nutrients (nitrate NO$_3$ (mmol N m$^{-3}$), ammonium NH$_4$ (mmol N m$^{-3}$), and silicate Si(OH)$_4$ (mmol Si m$^{-3}$)) and detritus (non-algal particles NAP (mmol N m$^{-3}$) and biogenic silica bSiO$_2$ (mmol Si m$^{-3}$)) (Fig. 2). Phytoplankton take up NO$_3$ and NH$_4$ by photosynthesis. In addition, diatoms utilize Si(OH)$_4$ in the silicification process. Microzooplankton graze on picoplankton. Mesozooplankton feed on diatoms, microzooplankton, and NAP.

To simulate the observed variation in phytoplanktonic chlorophyll to carbon ratio with growth conditions (light, nutrients, and temperature), we incorporated a photo-acclimation model into the physical-ecosystem model. Geider et al. (1987, 1998) developed a photo-acclimation model with single nutrient (nitrogen) and single phytoplankton
species. The photo-acclimation model used here is based on that of Moore et al. (2002) modified from Geider et al. (1998), which could be embedded in the multi-nutrient, phytoplankton, zooplankton, and detritus ecosystem model.

The governing equations and formulations of physical-ecosystem model and photo-acclimation model are described in Appendix A. The biogeochemical parameter values used in this study and their notations are provided in Table 1.

2.2 Optical model and radiative transfer model

We developed an optical module that explicitly represents spectrally-resolved inherent optical properties (IOPs, e.g., absorption, scattering, and attenuation) from the ecosystem model variables. Using a radiative-transfer model, we obtain the apparent optical properties (AOPs), such as diffuse attenuation, and radiometric quantities, as well as photosynthetically available radiation (PAR) and remotely sensed reflectance (ocean color).

The absorption coefficient is determined from the sum of the absorption coefficients of seawater, picoplankton and diatoms (based on their chlorophyll content, Chl1 and Chl2, respectively), non-algal particles (NAP), and colored dissolved organic matter (CDOM). Notable differences exist in the chlorophyll-specific absorption coefficient (m² mg⁻¹) of small and large phytoplankton, i.e., small phytoplankton have a higher chlorophyll-specific absorption coefficient and a steeper absorption spectra than large phytoplankton (Bricaud et al., 1983). In addition, the absorption spectra of a given phytoplankton functional group changes with intercellular chlorophyll concentration (the package effect, e.g., Duysens, 1956). Therefore, the chlorophyll-specific absorption coefficients by picoplankton and diatoms, \(a^*_\phi_1\) and \(a^*_\phi_2\), are modeled separately, taking into account their photo-adaptive state (e.g., their specific chlorophyll to carbon ratio) as follows (Fig. 3b):

\[
a^*_\phi_1(\lambda, z) = a^*_\phi_1(\text{high light})(\lambda) \\
\times (1 - \frac{\text{Chl1}(z)}{\theta_C^\text{max} - \theta_C^\text{min}}) + a^*_\phi_1(\text{low light})(\lambda) \times \frac{\text{Chl1}(z)}{\theta_C^\text{max} - \theta_C^\text{min}},
\]

\[
a^*_\phi_2(\lambda, z) = a^*_\phi_2(\text{high light})(\lambda) \\
\times (1 - \frac{\text{Chl2}(z)}{\theta_C^\text{max} - \theta_C^\text{min}}) + a^*_\phi_2(\text{low light})(\lambda) \times \frac{\text{Chl2}(z)}{\theta_C^\text{max} - \theta_C^\text{min}}.
\]
Table 1. The model parameters and values. Columns Case 1-1, Case 1-2, and Case 2 denote the parameter values used in non-spectral ecosystem model (Cases 1-1 and 1-2, without optics) and bio-optical model (Case 2), respectively.

where $a_{\lambda_1}^{\theta_1}(high\ light)$, $a_{\lambda_2}^{\theta_1}(low\ light)$, $a_{\lambda_2}^{\theta_2}(high\ light)$, and $a_{\lambda_2}^{\theta_2}(low\ light)$ are chlorophyll-specific absorption coefficients at low and high light by each phytoplankton, respectively, derived as described in Appendix B. $\theta_{min}^{\lambda}$ and $\theta_{max}^{\lambda}$ are the minimum and maximum phytoplanktonic chlorophyll to carbon ratios which are set to be 0.036 (mgChl mmolC$^{-1}$) and 1.2 (mgChl mmolC$^{-1}$), respectively, based on measurements in phytoplankton cultures (e.g., Falkowski et al., 1985; Guider et al., 1987; Cloern et al., 1995). The absorption co-
efficient by total phytoplankton $a_\phi$ is:

$$a_\phi(\lambda, z)(m^{-1}) = a_{\phi_1}(\lambda, z) \times \text{Chl1}(z) + a_{\phi_2}(\lambda, z) \times \text{Chl2}(z). \quad (3)$$

Based on observations (e.g., Iturriaga and Siegel, 1989; Roesler et al., 1989), the absorption coefficient by NAP ($a_{\text{NAP}}$) is calculated as:

$$a_{\text{NAP}}(\lambda, z)(m^{-1}) = a_{\text{NAP}}^+ (440) \times \text{NAP}(z) \times R_{\text{CN}} \times 12.0 \times 0.001 \times \exp [-0.011 \times (\lambda - 440)], \quad (4)$$

where $a_{\text{NAP}}^+ (440)$ is the carbon-specific absorption coefficient by NAP at 440 nm, assumed to be 0.1 (m$^2$ gC$^{-1}$) based on results of $a_{\text{NAP}}(440)$ [dry mass] = 0.036 ± 0.025 (m$^2$ g$^{-1}$) (Babin et al., 2003b; Table 5), and using a conversion of 2.6 (g gC$^{-1}$) (Babin et al., 2003a). Note that modeled NAP is in nitrogen (mmol m$^{-3}$) and is converted to carbon unit (gC m$^{-3}$). $R_{\text{CN}}$ is the ratio of carbon to nitrogen in phytoplankton (Table 1).

The total absorption coefficient by particles $a_p$ is then calculated:

$$a_p(\lambda, z) = a_\phi(\lambda, z) + a_{\text{NAP}}(\lambda, z). \quad (5)$$

Although effects of dissolved material on absorption in equatorial regions cannot be neglected (e.g., Pegau, 1997; Bricaud et al., 2002; Simeon et al., 2003), information concerning the distribution of CDOM in the equatorial Pacific is scarce. In addition, ratios of CDOM to dissolved organic matter (DOM) or DOM to dissolved organic carbon (DOC) are highly variable regionally (Mueller and Lange, 1989; Siegel et al., 2002). In this study, because CDOM is not explicitly treated in the model, the absorption coefficient by CDOM ($a_{\text{CDOM}}$) is assumed constant vertically and with a spectral dependence of (Fig. 3d):

$$a_{\text{CDOM}}(\lambda)(m^{-1}) = a_{\text{CDOM}}(440) \times \exp [-0.0145 \times (\lambda - 440)], \quad (6)$$

where $a_{\text{CDOM}}(440)$ is the absorption coefficient of CDOM at 440 nm and the value is fixed to 0.016 (m$^{-1}$) in this study, following observational values in the equatorial Pacific (0.012–0.019; Simeon et al., 2003).

Although the observed ratios of backscattering to scattering by particles ($b_{bp}/b_p$) are relatively low (0.5–3%) (e.g., Twardowski et al., 2001), backscattering plays an important role in ocean optics in general, and especially in determining ocean color. Assuming no contribution of CDOM to backscattering (e.g., Stramski et al., 2004), backscattering coefficients by algae and the co-varying particles are expressed as a function of POC concentration of small and large particles (POC1 and POC2, respectively) (mg m$^{-3}$), which consist of algal and associated NAP related to small and large phytoplankton functional groups, respectively. Results from previous studies indicate that the ratio of phytoplankton carbon to POC ($R_{\text{POC}}^p$) varies between about 25% and 40% in space and time (e.g., Eppley et al., 1992; DuRand et al., 2001; Gundersen et al., 2001; Oubelkheir et al., 2005). Considering these studies, we fix the ratio of picophytoplankton carbon to POC1 and diatom carbon to POC2 to 0.3. Backscattering by small and large POC (POC1 and POC2), $b_{bp_1}$ and $b_{bp_2}$, are formulated as follows (based on Fig. 4b in Stramski et al., 1999):

$$b_{bp_1}(\lambda, z)(m^{-1}) = \left( \frac{\text{POC1}(z)}{476935.8} \right)^{0.77} \times \left( \frac{\lambda}{510} \right)^{-0.5}, \quad (7)$$

$$b_{bp_2}(\lambda, z)(m^{-1}) = \left( \frac{\text{POC2}(z)}{17069.0} \right)^{-0.5}. \quad (8)$$

Backscattering by total particles $b_{bp}$ is expressed:

$$b_{bp}(\lambda, z)(m^{-1}) = b_{bp_1}(\lambda, z) + b_{bp_2}(\lambda, z) + b_{bg}. \quad (9)$$

where $b_{bg}$ is the background backscattering coefficient that implicitly reflects contribution by non-phytoplankton-covarying bacteria and other particles and was fixed to 0.00017 (m$^{-1}$), which is calculated using backscattering coefficients from Stramski and Kiefer (1991) and a field-based background heterotrophic bacterial concentration of $7 \times 10^{11}$ (m$^{-3}$) from Cho and Azam (1990) (as in Behrenfeld and Boss, 2006).

Total scattering by particles $b_p$ is calculated as follows:

$$b_p(\lambda, z) = b_{\text{POC}}^p \times b_{bp_1} \times b_{bp_2} \times b_{bg} \times (1 - R_{\text{CDOM}}^p \times b_{\text{NAP}} \times (b_{bp_1}(\lambda, z) + b_{bp_2}(\lambda, z))) + b_{bg} \times b_{bg}, \quad (10)$$

where $b_{bp_1}$, $b_{bp_2}$, $b_{\text{NAP}}$, and $b_{bg}$ are the backscattering ratios for picophytoplankton (0.01; based on near surface observations in open-ocean waters in Twardowski et al., 2001), diatoms (0.006; based on near-surface coastal observations in Twardowski et al., 2001 and Boss et al., 2004), NAP (0.015; e.g., Twardowski et al., 2001) and other background particles (0.02; e.g., Twardowski et al., 2001), respectively.

Beam attenuation coefficient by particles $c_p$ is expressed as follows:

$$c_p(\lambda, z)(m^{-1}) = a_p(\lambda, z) + b_p(\lambda, z). \quad (11)$$

Total absorption, scattering, and backscattering coefficients, $a$, $b$, and $c_p$ are calculated:

$$a(\lambda, z)(m^{-1}) = a_{sw}(\lambda) + a_p(\lambda, z) + a_{\text{CDOM}}(\lambda), \quad (12)$$

$$b(\lambda, z)(m^{-1}) = b_{sw}(\lambda) + b_p(\lambda, z), \quad (13)$$

$$c_p(\lambda, z)(m^{-1}) = b_{\text{NAP}} \times b_{bp_1}(\lambda) \times b_{bp_2}(\lambda), \quad (14)$$

where $a_{sw}$ and $b_{sw}$ are absorption and backscattering coefficients by seawater, respectively. The coefficients depend on wavelengths and are obtained from Pope and Fry (1997) with the correction for salts (Morel, 1974; Boss and Pegau, 2001) (Figs. 3a and 4a). $\tilde{b}_{bp_{sw}}$ is the backscattering ratio for seawater (0.5; e.g. Morel 1974).
The model-derived spectral absorption, a Fournier-Forand phase function with the model-derived particulate backscattering ratio (Fournier and Forand, 1994; Mobley et al., 2002), and sky and surface wave conditions, are all input into a radiative transfer model which calculates the underwater light field from which the downwelling photosynthetically available radiation (PAR) (W m\(^{-2}\)) is obtained and used as an input to light-sensitive processes in the ecosystem model. For a radiative transfer model, we used Ecolight (Sequoia Scientific, Inc.), a new and reduced version of the Hydrolight radiative transfer model (see Mobley and Sundman (2005a, b) for details of Ecolight). In Ecolight, the irradiance is azimuthally averaged and is used to reduce the computation load. A semi-empirical sky model based on RADTRAN (Gregg and Carder, 1990), which is embedded in Ecolight, is used to calculate the hourly irradiance at the sea surface for the appropriate date and location, assuming no cloud cover and a surface wave field consistent with a daily-averaged wind speed of 5 m s\(^{-1}\).

2.3 Experimental design

The physical-ecosystem simulation model, photo-acclimation model, optical model and radiative transfer model (Ecolight) are linked (Fig. 1) and applied to the equatorial Pacific upwelling region (5\(^\circ\)S–5\(^\circ\)N, 90\(^\circ\)W–180\(^\circ\)W, the “Wyrtki Box”; Wyrtki, 1981). The physical forcing and most of the biogeochemical parameter values are the same as in Chai et al. (2002) (Table 1), although the photo-acclimation model was not introduced by Chai et al. (2002). Hourly incident sky radiance on 30 June, which represents well the annual-mean condition in this oceanic region, is used to drive Ecolight. The short time step of the model (three hours) is needed to simulate diurnal cycles of biology, particularly for phytoplankton, because the photosynthesis is controlled by irradiance at each time step. We tested increasing the time step and found that it could be no longer than three hours before significant differences were observed. Shorter time steps did not change the simulation markedly and would represent an undesirable increase in computation load.

Next, steady-state results, obtained by running the model up to 1000 days with the area-averaged (5\(^\circ\)S–5\(^\circ\)N, 90\(^\circ\)W–180\(^\circ\)W) annual-mean vertical velocity from the ocean general circulation model (Chai et al., 1996) and the area-averaged (5\(^\circ\)S–5\(^\circ\)N, 90\(^\circ\)W–180\(^\circ\)W) annual-mean vertical diffusivity based upon the formulation by Pacanowski and Philander (1981) (Fig. 1 in Chai et al., 2002), are compared to measurements in the equatorial Pacific.

We set all the parameter values in the photo-acclimation model to the same as in previous studies (Geider et al., 1998; Moore et al., 2002) (Table 1). Most of the parameter values in the ecosystem model are set to the same as in Chai et al. (2002). Given that the maximum specific grazing rate by mesozooplankton (G\(_{2\text{max}}\)) has a relatively large uncertainty in its value, and the estimated value differs among previous studies with the same ecosystem model (Chai et al., 2002; Jiang et al., 2003; Fujii and Chai, 2007), we modify this parameter’s value (tune it) so that the modeled surface nitrate and silicate concentrations would be the closest to the standard measurements in the equatorial Pacific of 6 (mmolN m\(^{-3}\)) and 3 (mmolSi m\(^{-3}\)), respectively (Figs. 5b, d), which were derived from the US JGOFS EqPac observation in August-September (Survey II; TT011) and October
3 Results and discussion

3.1 Bio-optical model results

3.1.1 Biological properties

With the parameter values obtained by the procedure described in the previous subsection (Table 1), the tuned model is capable of reproducing well the measured vertical features in biogeochemical properties in the equatorial Pacific upwelling region, i.e., consistently higher NO3 than Si(OH)4 concentration and surface maximum in net community production (blue lines in Figs. 5b–d; e.g., Barber et al., 1996).

The model also reproduces a subsurface chlorophyll maximum of 0.34 (mgChl m−3) at around 65–70 m depth (blue line in Fig. 5e), which agrees with the observed maximal value of 0.4 (mgChl m−3) (Dupouy et al., 2003). The modeled phytoplanktonic chlorophyll to carbon ratio decreases with PAR, or increases exponentially with depth (Fig. 7), which is also consistent with observations (e.g., Chavez et al., 1991).

3.1.2 Optical properties

Absorption

Modeled absorption by phytoplankton at 440 nm \( (a_\phi(440)) \) has its subsurface maximum of 0.023 (m−1) (Fig. 6a), which agrees well with observations (0.021±0.001 (Simeon et al., 2003) and 0.023 (m−1) (Dupouy et al., 2003)). The modeled phytoplanktonic chlorophyll to carbon ratio decreases with PAR, or increases exponentially with depth (Fig. 7), which is also consistent with observations (e.g., Chavez et al., 1991).
atoms ($a_{\phi 2}(440))$, indicating low but significant contribution of NAP to the total particulate absorption in the equatorial Pacific (Fig. 6a). The modeled NAP contribution to total particle absorption reproduces the observed increase with depth, from 8% in the surface and up to 33% at the bottom of the euphotic layer (120 m depth) (Fig. 6b). The mean NAP contribution to total particle absorption in the euphotic layer is 17%, which is consistent with the measurements of 10–17% (Dupouy et al., 1997 and 2003; Parslow et al., 1998; Bricaud et al., 2002). The model results of $a_{\phi}(440)$, $a_{\text{NAP}}(440)$ and NAP contribution to total particle absorption all indicate linear increase with depth from the surface to subsurface layer. However, the in-situ measurements show wide horizontal variation in these components, both zonally (Simeon et al., 2003) and meridionally (Dupouy et al., 2003) in the equatorial Pacific, and further observational data of the optical components are necessary for improvement of simulation capability by the optical model.

Colored dissolved organic matter (CDOM) also plays an important role in absorption (e.g., Pegau, 1997; Bricaud et al., 2002; Simeon et al., 2003). We fixed the absorption coefficient by CDOM at 440 nm ($a_{\text{CDOM}}(440)$) vertically to 0.016 (m$^{-1}$), within the observed range (0.012–0.019 (m$^{-1}$); Simeon et al., 2003). Modeled contribution of CDOM to total absorption at 440 nm ($a(440)$) is 59–97% and tends to increase with depth, consistent with the measurements (50% at surface and 100% below chlorophyll maximum; Simeon et al., 2003). CDOM (and DOM) dynamics are not currently included in the model and thus its relative contribution to absorption is determined by the variability of the particulate absorption.

**Backscattering**

Modeled backscattering coefficients by small and large POC (POC1 and POC2, respectively) at 660 nm ($b_{\text{bp1}}(660)$ and $b_{\text{bp2}}(660)$, respectively) are highest at surface and decrease with depth (Fig. 8). Contribution of POC1 to total particle backscattering is 53–66%. The contribution of pico-plankton to backscattering is less dominant than that to absorption, but it is still higher than that of diatoms because of its small size and larger contribution to POC (Stramski and Kiefer, 1991).

**Beam attenuation**

Beam attenuation, especially by particles ($c_p=a_p+b_p$), has been often measured in the equatorial Pacific (e.g., Chung et al., 1996; Bishop, 1999; Gardner et al., 2003; Behrenfeld and Boss, 2006). As the contribution of particulate absorption is negligible at 660 nm (Figs. 3b and c), we can assume that $c_p$ is due to scattering by particles. The modeled vertical profile of $c_p$ is similar to the vertical profiles of backscattering coefficients by particles and POC concentration (Figs. 8 and 9b, c), all of which have the maximum at surface and decrease with depth. Both modeled POC and $c_p$ agree with measurements in the equatorial Pacific upwelling region (Fig. 9a), which warrants the applicability of the relation between POC and $c_p$ (Eqs. (7) and (8)) to this region.

3.1.3 Comparison of model results: with and without optics

In ecosystem models that are not coupled to an optical model, values of biogeochemical parameters are tuned to mini-
mize model-data misfits with vertical profiles of nutrient and chlorophyll concentrations and net community production in the euphotic layer (Figs. 5b, c, d). Vertical profile of PAR was not used to calibrate parameters in previous ecosystem models with constant light attenuation coefficients. Modeled zooplankton biomass and NAP concentration cannot be validated because very few corresponding observational data exist.

In order to examine the value of incorporating a full optical and radiative transfer model into the ecosystem model, we compare two cases, Cases 1 and 2. Case 1 uses only a rudimentary wavelength integrated model for the underwater light field (Eq. 15 below), while Case 2 is the full model using EcoLight to obtain the spectrally resolved underwater light field as described in Sect. 3.1.2.

The model structure in Case 1 was modified from Case 2, as follows. PAR is computed from:

\[
\text{PAR}(z) \text{(Wm}^{-2}\text{)} = \text{PAR}(0) \times \exp \left(-k_1 z - k_2 \int_0^z (\text{Chl}1(z) + \text{Chl}2(z))dz\right),
\]

where \(k_1\) is the light attenuation coefficient due to water (0.046 (m\(^{-1}\))) and \(k_2\) is the light attenuation coefficient by chlorophyll (0.048 (mgChl m\(^{-1}\))\(^{-1}\); e.g., Chai et al., 2002). We carry out two case studies with the non-spectral ecosystem model, Cases 1-1 and 1-2.

In Case 1-1, the light attenuation coefficients are set to the same as in Chai et al. (2002) (Table 1). In this case, as in most previous ecosystem modeling studies, observed PAR values and associated decreases with depth are not referred to in tuning model parameters. Therefore, the parameters are tuned to minimize model-data misfits with vertical profiles of nutrient and chlorophyll concentrations and net community production, which requires modification of the microzooplankton maximum specific grazing rate (\(G_{\text{max}}\)) from Case 2 by a factor of 1.2 (Table 1). The model results show similar vertical profiles of Si(OH)\(_4\) concentration and net community production, relatively low surface NO\(_3\) concentration, and higher and deeper chlorophyll maximum, compared with those in Case 2, although the results of both models are within the observations (Figs. 5b, c, d, e). The modeled PAR in Case 1-1 is higher than in Case 2 by a factor of 1.7 and overestimates the observation (Fig. 5a). The modeled surface NO\(_3\) concentration and maximal value of chlorophyll concentration cannot be decreased by changing any parameters other than light attenuation coefficients.

In Case 1-2, vertical profiles of PAR, nutrient and chlorophyll concentrations, and net community production are used for tuning model parameters. The light attenuation coefficients are increased relative to those in Chai et al. (2002), by a factor of 1.2 in \(k_1\) and 1.3 in \(k_2\) (Table 1), to reproduce observed vertical profiles of PAR. Once the light attenuation coefficients are elevated, we can set values of the other parameters to the same as in Case 2 (Table 1) for the best-fit model results. However, without information for NAP concentration, it is difficult to estimate parameter values associated with zooplankton, such as maximum specific grazing rates, because of pronounced nitrogen flow from zooplankton to NAP via fecal pellets. In Case 2 with the bio-optical model, we tune the maximum specific grazing rates so that the model can reproduce the measured contribution of NAP to absorption by total particles by 10–17% (Dupouy et al., 1997 and 2003; Parslow et al., 1998; Bricaud et al., 2002) (Fig. 6b), as described in Sect. 3.1.2.

Phytoplankton community assemblage can also be reproduced by the model with optics (Case 2). In Chai et al. (2002), using the non-spectrally-resolved ecosystem model, they tuned the water-column phytoplankton assemblage so that the percentage of diatoms to the total phytoplankton biomass is nearly 16%, referring to the observed ranges from 5% to 20% (Bidigare and Ondrusek, 1996). With the spectrally-resolved bio-optical model (Case 2), we could tune vertical phytoplankton assemblage more accurately, referring to not only measurements of each phytoplankton biomass but also those of contribution of diatoms to total phytoplankton derived from optical properties (absorption and backscattering).

These results suggest that both ecosystem model results with or without optics can reproduce the observed fundamental biogeochemical properties in the equatorial Pacific, as long as the correct diffuse light attenuation is used. Since the PAR data are not consistent with the simple chlorophyll formulation previously used in Chai et al. (2002), another source of diffuse light attenuation is needed for the model that can take into account contributions by NAP and CDOM. Our bio-optical model provides such a value.

In addition, the coupled model results illustrate its capability to be constrained using observations of optical variables and thus its ability in improving model performance, which currently cannot be done with available biological properties alone. Additional constituents, which should be added to future ecosystem models, such as DOM, bacteria, and coccoliths (e.g., Fujii and Chai, 2007), are likely to improve the optics-simulation model fit assuming relevant data on their abundance can be obtained.

While we were able to reproduce most of the observations by simply changing the diffuse attenuation values in the model lacking optics (Case 1-2), this approach is not likely to work in temporally varying simulations where the diffuse attenuation coefficient changes in time; any changes in the relative proportion of the biogeochemical variables contributing to absorption (and to a lesser degree to backscattering) would result in changes in the diffuse attenuation parameters in Eq. (15). Simulating these changes requires having the appropriate biogeochemical constituents and related optical properties, most of which are captured by the bio-optical model (with the important exception of CDOM).
Table 2. Sensitivity of model results to optical parameters: Carbon-specific absorption coefficient by NAP at 440 nm ($a_{\text{NAP}}^+(440)$), absorption coefficient by CDOM at 440 nm ($a_{\text{CDOM}}(440)$), background backscattering coefficient ($b_{\text{bbg}}$), ratio of phytoplankton carbon to POC ($R_{\text{POC}}^+$), backscattering ratio for picoplankton ($\tilde{b}_{p1}$), diatoms ($\tilde{b}_{d,p2}$), NAP ($\tilde{b}_{p,NAP}$), and background particles ($\tilde{b}_{p,bbg}$). Values in parentheses denote model results from a control run with bio-optical model. Euphotic layer depth is defined as a depth of 0.1% of sea surface.

3.2 Optics as a constraint for determining variables and related parameters – sensitivity to optical parameters

The parameter values chosen in this study for the optical model are based on observations (Table 1), but the observed values have substantial variability that arises from environmental and methodological variability. To elucidate how model results are affected by variations in the optical model parameters, we conduct a sensitivity study of the model to those parameters by changing their values individually by 30% of their standard values. Such variability encompasses the bulk of observed values (Table 2).

We find the model results of biogeochemical properties, i.e., surface NO$_3$, Si(OH)$_4$, and maximum chlorophyll and its associated depth, to be most sensitive to changes in the absorption coefficient by CDOM at 440 nm ($a_{\text{CDOM}}(440)$). The surface NO$_3$ increases and Si(OH)$_4$ decreases with the increase of $a_{\text{CDOM}}(440)$, due to an increase in contribution by diatoms when $a_{\text{CDOM}}(440)$ is higher. The maximum chlorophyll decreases and appears at a deeper layer of 85 m with an $a_{\text{CDOM}}(440)$ increase. These model results reveal that the CDOM concentration strongly affects phytoplankton community structure and its dynamics. While CDOM’s inherent effects on backscattering and hence beam attenuation coefficient at 660 nm ($C_p(660)$) are negligible, an increase of $a_{\text{CDOM}}(440)$ yields a $C_p(660)$ decrease due to a decrease in small algal POC. The modeled euphotic layer depth, defined as a depth of 0.1% light level of sea surface, decreases from 120 m to 110 m by varying $a_{\text{CDOM}}(440)$ from 0.011 to 0.021 (m$^{-1}$), primarily as a result of enhanced absorption by CDOM. The change of the euphotic layer depth is relatively small because PAR is more controlled by absorption by water than absorption by underwater particle and CDOM concentration. However, the euphotic layer depth is more sensitive to $a_{\text{CDOM}}(440)$ than to the other optical parameters due to significant absorption by CDOM at short wavelengths around 400 nm, at which absorption by water is negligible (Figs. 3a and d).

The observed sensitivity to CDOM concentration is the result of CDOM absorbing light that would otherwise be absorbed by phytoplankton. This effect is more pronounced on picoplankton as they have a relatively higher portion of their energy absorbed in the blue wavelength where CDOM absorbs (they are less packaged and thus have a higher blue to red absorption ratio; Bricaud and Stramski, 1990). Changes in the relative abundance of small and large phytoplankton result in a change in the biogeochemical properties of the upper ocean since their metabolic requirements and interaction with other trophic levels are different.

Variation in other optical parameters also contribute to changes in the model results, but their impact is smaller than that of $a_{\text{CDOM}}(440)$. The carbon-specific absorption coefficient by NAP at 440 nm ($a_{\text{NAP}}^+(440)$) has weaker but similar effects on surface nutrient and maximum chlorophyll con-
The modeled $a_{\text{NAP}}/a_p(440)$ is the most sensitive to $a_{\text{NAP}}(440)$, changing by a factor of 2 from 0.10 to 0.20. The modeled $C_p(660)$ is affected most significantly by the ratio of phytoplankton to particulate organic carbon ($R_{\text{POC}}^\phi$). The modeled euphotic layer depth does not change from the standard value of 115 m by changing any optical parameters except for $a_{\text{NAP}}(440)$, which indicates the important role of absorption in the lower layer below chlorophyll maximum in determining the euphotic layer depth. Varying any of the backscattering ratios, regardless of particle type, does not affect the modeled biogeochemical properties but does influence $C_p(660)$. However, the sensitivity of $C_p(660)$ to the backscattering ratios depends on particle type, being stronger for NAP and picoplankton and weaker for diatoms and background particles, reflecting the higher backscattering coefficient by picoplankton than by diatoms.

The overall sensitivity study shows that narrowing the observed ranges of optical parameters above is required to reduce uncertainties in reproducing biogeochemical properties. In addition, the above analysis suggests that although the dynamics of neither CDOM nor bacteria are currently incorporated explicitly in the model, embedding CDOM as a state variable in the ecosystem model should be given priority over bacteria to improve simulating bio-optical interactions.

4 Summary and remarks

We developed an ecosystem model that explicitly represents biogeochemically and optically two phytoplankton and two zooplankton functional groups, as well as multiple nutrients and non-algal particles (NAP). We applied the model to the equatorial Pacific upwelling region and found that utilizing an optical model to convert from ecosystem model state variables to optical parameters and a realistic subsurface light provides:

(1) more data to compare model output with providing a more rigorous test on model formulation and choice of parameter values, especially for those that are difficult to measure in high resolution in time and space, (2) the required input to obtain a realistic subsurface light field by linking the optics to a radiative-transfer model (Ecolight), and (3) improved simulation realism with respect to key biogeochemical processes, such as photosynthesis, which are crucial for assessing oceanic carbon cycling and food web dynamics. The additional optical measurements, being routinely available from research vessels, autonomous platforms, and space-borne observations, can now be used directly for comparison and testing of the output of our new coupled bio-optical model. This is an improvement over the limited number of variables that can be used to test our previous ecosystem models with no explicit optical properties.

Model sensitivity studies on optical parameters suggest that CDOM may have an important role in phytoplankton dynamics, nutrient cycling, and light field in the euphotic layer. Incorporating radiative transfer models to ecosystem models would also contribute to improving the realistic simulations of physical-bio-optical interactions such as chlorophyll modulation of water temperature (e.g., Nakamoto et al., 2000), although these capabilities were not tested here. In the future, real time optical data should be obtained and used in an assimilation mode, increasing the realism of ecosystem simulations such as prediction of the harmful algal bloom dynamics in coastal regions, a prediction that is extremely useful for monitoring near shore water quality and its impact on marine living resources and aquaculture.
Appendix A

Physical-ecosystem model

A1 Governing equations

The model equations describing each compartment all take the form:

$$\frac{\partial C_i(z)}{\partial t} \left[ \text{mmol} \, \text{m}^{-3} \, \text{day}^{-1} \right] \text{ or } \left[ \text{mg} \, \text{m}^{-3} \, \text{day}^{-1} \right] = \text{PHYSICS}(C_i(z)) + \text{BIOLOGY}(C_i(z)), \quad (A1)$$

$$i = 1, \ldots, 13.$$

The model state variables ($C_i$) are picoplankton ($P1$ (mmolN m$^{-3}$), $C1$ (mmolC m$^{-3}$), and Chl1 (mgChl m$^{-3}$)), diatoms ($P2$ (mmolN m$^{-3}$), $C2$ (mmolC m$^{-3}$), and Chl2 (mgChl m$^{-3}$)), microzooplankton ($Z1$ (mmolN m$^{-3}$)), mesozooplankton ($Z2$ (mmolN m$^{-3}$)), nitrate (NO$_3$ (mmolN m$^{-3}$)), ammonium (NH$_4$ (mmolN m$^{-3}$)), silicate (Si(OH)$_4$ (mmolSi m$^{-3}$)), non-algal particles (NAP (mmolN m$^{-3}$)), and biogenic silica (bSiO$_2$ (mmolSi m$^{-3}$)).

The term PHYSICS($C_i$) represents the contribution to the concentration change due to physical processes, including vertical advection and eddy diffusion:

$$\text{PHYSICS}(C_i(z)) \left[ \text{mmol} \, \text{m}^{-3} \, \text{day}^{-1} \right] \text{ or } \left[ \text{mg} \, \text{m}^{-3} \, \text{day}^{-1} \right] = -W \frac{\partial C_i(z)}{\partial z} + \frac{\partial}{\partial z} \left( A_{Tv} \frac{\partial C_i(z)}{\partial z} \right), \quad (A2)$$

where $W$ is vertical velocity, and $A_{Tv}$ is vertical coefficient. The values are the same as Chai et al. (2002). The term BIOLOGY ($C_i$) represents biological sources and sinks of that compartment. In the euphotic zone (the upper 120 m), the biological terms, BIOLOGY($C_i$) are:

$$\text{BIOLOGY}(P1(z)) \left[ \text{mmolN} \, \text{m}^{-3} \, \text{day}^{-1} \right] = NP1(z) + RP1(z) - G1(z) \times \frac{C1(z)}{P1(z)}, \quad (A3)$$

$$\text{BIOLOGY}(C1(z)) \left[ \text{mmolC} \, \text{m}^{-3} \, \text{day}^{-1} \right] = PC1(z) - \xi P1(z) \left( NP1(z) + RP1(z) \right) - G1(z) \times \frac{C1(z)}{P1(z)}, \quad (A4)$$

$$\text{BIOLOGY}(\text{Chl1}(z)) \left[ \text{mgChl} \, \text{m}^{-3} \, \text{day}^{-1} \right] = \rho \text{Chl1}(z) \left( NR1(z) + RP1(z) \right) - G1(z) \times \frac{\text{Chl1}(z)}{P1(z)}, \quad (A5)$$

$$\text{BIOLOGY}(P2(z)) \left[ \text{mmolN} \, \text{m}^{-3} \, \text{day}^{-1} \right] = NP2(z) + RP2(z) - G2(z) - \frac{\partial}{\partial z} \left( \gamma P2(z) \right) \times W P2(z), \quad (A6)$$

$$\text{BIOLOGY}(C2(z)) \left[ \text{mmolC} \, \text{m}^{-3} \, \text{day}^{-1} \right] = PC2(z) - \xi P2(z) \left( NP2(z) + RP2(z) \right) - G2(z) \times \frac{C2(z)}{P2(z)} - \frac{\partial}{\partial z} \left( \gamma P2(z) \right), \quad (A7)$$

$$\text{BIOLOGY}(\text{Chl2}(z)) \left[ \text{mgChl} \, \text{m}^{-3} \, \text{day}^{-1} \right] = \rho \text{Chl2}(z) \left( NR2(z) + RP2(z) \right) - G2(z) \times \frac{\text{Chl2}(z)}{P2(z)} - \frac{\partial}{\partial z} \left( \gamma P2(z) \right), \quad (A8)$$
BIOLOGY \((Z1(z)) [\text{mmolN m}^{-3} \text{day}^{-1}] = \gamma G_1(z) - \frac{G_3(z)}{\text{grazing on P1}} - \frac{\text{reg}_1 Z1(z)}{\text{excretion}}\) \hspace{1cm} (A9)

\[
\xi_2 = \frac{\rho_2 Z_1(z)}{\rho_1 P_2(z) + \rho_2 Z_1(z) + \rho_3 NAP(z)},
\]

\[
\xi_3 = \frac{\rho_3 NAP(z)}{\rho_1 P_2(z) + \rho_2 Z_1(z) + \rho_3 NAP(z)}.
\]

Appendix B

Chlorophyll-specific absorption coefficients by phytoplankton in high and low light environments

We need highest and lowest chlorophyll-specific absorption coefficients by picoplankton \(a_{\phi 1}^{*}(\text{high light}, \lambda)\) and \(a_{\phi 1}^{*}(\text{low light}, \lambda)\) and diatoms \(a_{\phi 2}^{*}(\text{high light}, \lambda)\) and \(a_{\phi 2}^{*}(\text{low light}, \lambda)\) to obtain chlorophyll-specific absorption coefficients at each wavelength and depth from Eqs. (1) and (2) in Sect. 2.2. Although many previous studies have measured the chlorophyll-specific absorption coefficients by various phytoplankton species, the values are highly variable, especially for picoplankton in the surface water at around 440 nm (e.g., Moore et al., 1995; Allali et al., 1997; Culver and Perry, 1999; Ciotti et al., 2002; Devred et al., 2006). This implies complicated small phytoplankton assemblage with different pigment packaging in reality while the small phytoplankton (P1) is represented by one species (picoplankton) in the model. In addition, the measured specific absorption coefficient by small phytoplankton is often obtained by dividing the absorption coefficient by not only chlorophyll but also other pigments such as pheophytin (pheopigments).

The highest chlorophyll-specific absorption coefficient by diatoms at 440 nm \(a_{\phi 2}^{*}(\text{high light}, 440)\) is set to 0.012 \((\text{m}^2 \text{mg}^{-1})\), based on an observed mean value of microplankton in the surface water (Fig. 7 in Ciotti et al., 2002). We assume that a ratio of highest to lowest chlorophyll-specific absorption coefficient at 440 nm in the equatorial Pacific is around 1.5 for each phytoplankton, attributing to observed chlorophyll-specific absorption coefficients by total phytoplankton at 440 nm in each depth, which varies from 0.07 \((\text{m}^2 \text{mg}^{-1})\) in the surface water \(a_{\phi 1}^{*}(\text{high light}, 440)\) to 0.045 \((\text{m}^2 \text{mg}^{-1})\) at the bottom of the euphotic layer \(a_{\phi 1}^{*}(\text{low light}, 440)\) (Fig. 5 in Allali et al., 1997). Therefore, \(a_{\phi 2}^{*}(\text{low light}, 440)\) is estimated to be about 0.008 \((\text{m}^2 \text{mg}^{-1})\). We also assume that a ratio of picoplankton to total phytoplankton chlorophyll and that of diatoms to total phytoplankton chlorophyll are around 0.83 and 0.17, respectively, and are uniform with depth (e.g., Chavez, 1989; Peña et al., 1990; Bidigare and Ondrusek, 1996). Based on Ciotti et al. (2002), Devred et al. (2006) reconstructed the specific absorption spectra of phytoplankton communities as a linear combination of absorption spectra of small and large cells:

\[
a_{\phi}^{*}(\lambda, z) = F a_{\phi 1}^{*}(\lambda, z) + (1 - F) a_{\phi 2}^{*}(\lambda, z),
\]

where \(F\) is the phytoplankton size fraction.

With the assumption above, we estimate highest and lowest chlorophyll-specific absorption coefficients by picoplankton at 440 nm \(a_{\phi 1}^{*}(\text{high light}, 440)\) and \(a_{\phi 1}^{*}(\text{low light}, 440)\), respectively as follows:

\[
a_{\phi 1}^{*}(\text{high light}, 440)[\text{m}^2 \text{mg}^{-1}] = \left[ a_{\phi}^{*}(\text{high light}, 440) - 0.17 \times a_{\phi 2}^{*}(\text{high light}, 440) \right] \frac{0.83}{0.012 - 0.008},
\]

\[
a_{\phi 1}^{*}(\text{low light}, 440)[\text{m}^2 \text{mg}^{-1}] = \left[ a_{\phi}^{*}(\text{low light}, 440) - 0.17 \times a_{\phi 2}^{*}(\text{low light}, 440) \right] \frac{0.83}{0.012 - 0.008}.
\]

From these equations, we derive \(a_{\phi 1}^{*}(\text{high light}, 440)\) of 0.082 \((\text{m}^2 \text{mg}^{-1})\) and \(a_{\phi 1}^{*}(\text{low light}, 440)\) of 0.053 \((\text{m}^2 \text{mg}^{-1})\), which agree well with the observed chlorophyll-specific absorption coefficients by picoplankton (e.g., Ciotti et al., 2002). The highest and lowest chlorophyll-specific absorption coefficients by picoplankton and diatoms at other wavelengths are derived by fitting spectral profiles of Ciotti and Bricaud (2006) and Ciotti et al. (2002), respectively, to coincide at 440 nm.
