ABSTRACT

Recently, we have proposed a spin quantum cross structure (SQCS) device toward the realization of novel spintronics devices. In this paper, we have investigated thermoelectric effects in point contacts (PCs) of Ni ferromagnetic metals using SQCS devices, theoretically and experimentally. The calculated results show that the thermoelectric voltage V_q changes from 0.48 mV to 2.12 mV with the temperature difference of PCs increasing from 10 K to 50 K. Also, the magnitude of the theoretical thermoelectric voltage agrees very well with that of the experimental result. PCs of SQCS devices with Ni electrodes can serve as spin dependent thermobatteries.

INTRODUCTION

Many researchers have paid much attention to point contacts (PCs) of ferromagnetic metals since conductance quantization in units of e^2/h was discovered at PCs of Ni ferromagnetic metals [1]. Also, some researchers report that PCs of Ni ferromagnetic metals show large magnetoresistance in the ballistic regime [2]. However, thermal characteristics in PCs of ferromagnetic metals have almost not been studied even though those in PCs of normal metals have been extensively studied. In this paper, we have theoretically investigated thermoelectric effects in PCs of Ni ferromagnetic metals using spin quantum cross structure (SQCS) devices, and we have verified the thermoelectric effects in PCs of Ni ferromagnetic metals experimentally. The SQCS device consists of two ferromagnetic metal thin films with their edges crossing, and sandwiches a few molecules and atoms [3-6]. The junction area made of two edges can be scaled down to nanometer size due to the good resolution in making films by the metal-deposition rate, ranging from 0.01 nm/s to 1 nm/s. We have already realized the SQCS device with Ni ferromagnetic electrodes [6].

THEORY AND EXPERIMENTAL RESULTS

The models of SQCS devices with two-dimensional (2D) electrodes are shown in figure 1(a). We have analyzed the spin dependent thermoelectric characteristics within the framework of the Anderson Hamiltonian. We study the current-voltage (I - V) characteristics of SQCS devices with a molecule sandwiched between two Ni magnetic electrodes. The molecule is assumed to have two energy levels. We also assume that the molecule does not flip the spin of an electron passing through the energy level. The energy diagram for the SQCS device model is also shown in figure 1(b). Notice that this model can be applied to SQCS devices without any molecules sandwiched between the two Ni magnetic electrodes. In the case that there are no sandwiched molecules, both electrodes are in contact with each other directly and the conductance channels (energy levels) are formed in the gap between the electrodes. The energy

levels formed in the gap between the electrodes can be regarded as energy levels which the virtual molecule has, as if the virtual molecule was in the gap. This concept has been verified to work very well in a previous paper [6].

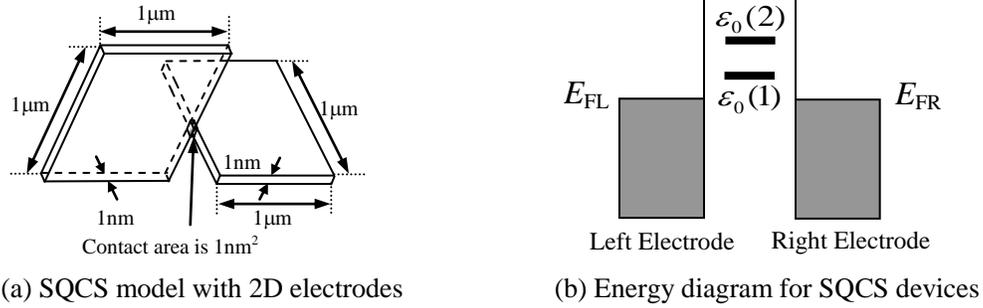

Figure 1. Schematic illustration of (a) SQCS device models with two-dimensional (2D) electrodes and (b) the energy diagram for SQCS devices.

The Anderson Hamiltonian is described as follows:

$$\begin{aligned}
 H &= H_{\text{Electrodes}} + H_{\text{mole}} + H_t, \\
 H_{\text{Electrodes}} &= \sum_{\alpha=L,R} \sum_{k,\sigma} \varepsilon_{k\sigma} c_{\alpha,k\sigma}^+ c_{\alpha,k\sigma}, \\
 H_{\text{mole}} &= \sum_{i,\sigma} \varepsilon_0(i) a_{i,\sigma}^+ a_{i,\sigma}, \\
 H_t &= \sum_{\alpha=L,R} \sum_{k,\sigma} \sum_{i,\sigma} (V_{\alpha}^{\sigma} c_{\alpha,k\sigma}^+ a_{i,\sigma} + \text{H.c.}).
 \end{aligned} \tag{1}$$

$H_{\text{Electrodes}}$ is the Hamiltonian of both Ni electrodes, $\varepsilon_{k\sigma} = \frac{\hbar^2 \mathbf{k}^2}{2m}$, m is the free electron mass, and \hbar is Planck's constant h divided by 2π . The band of itinerant d-like electrons of Ni is assumed to be parabolic with the free electron mass [7]. The wave vector \mathbf{k} is a 2D vector in 2D electrodes. $c_{\alpha,k\sigma}^+$ and $c_{\alpha,k\sigma}$ are creation and annihilation operators for electrons of wave vector \mathbf{k} and spin index σ in α electrode. α indicates the left or right electrode. The creation and annihilation operators obey the standard fermion anticommutation rules. H_{mole} is the Hamiltonian of a molecule sandwiched between both the electrodes, and $\varepsilon_0(i)$ represents the i -th energy level of eigenstates of the molecule as shown in figure 1(b). In this paper, we consider the case that both electrodes of SQCS devices are in contact with each other directly. Then, the two energy levels were set to be $\varepsilon_0(1) = 10 \text{ meV}$, $\varepsilon_0(2) = 20 \text{ meV}$, estimated from Fermi levels $E_{\text{FL}}, E_{\text{FR}}$ of each electrode, respectively. These energy levels are assumed to be quantized levels formed in a narrow gap between the electrodes. The Fermi levels E_{FL} and E_{FR} of each electrode were assumed to be equal and we used the value of 9.071 eV for the Ni Fermi level [8]. The value of 260 meV was used for the exchange splitting of Ni [9]. $a_{i,\sigma}^+$ and $a_{i,\sigma}$ are creation and annihilation operators for electrons of spin index σ in the i -th energy level. These operators also obey the

standard fermion anticommutation rules. H_t is the transfer Hamiltonian between the sandwiched molecule and each electrode, V_α^σ is the spin-dependent transfer matrix between the molecule and electrons of spin index σ in α electrode. This value determines the coupling strength between each electrode and the molecule. Considering H_t as a perturbation, we have investigated the I - V characteristics from right to left electrode. After tedious manipulation, the current $I_{\uparrow\uparrow}$ ($I_{\uparrow\downarrow}$) from right to left electrode is as follows:

$$I_{\uparrow\uparrow} = \frac{e}{h} \int_{E_{\text{FR}}}^{E_{\text{FR}}+eV} d\varepsilon \sum_i \left(\frac{4\Gamma_{\text{L}}^+(\varepsilon) \Gamma_{\text{R}}^+(\varepsilon)}{[\varepsilon - \varepsilon_0(i)]^2 + [\Gamma^{++}(\varepsilon)]^2} + \frac{4\Gamma_{\text{L}}^-(\varepsilon) \Gamma_{\text{R}}^-(\varepsilon)}{[\varepsilon - \varepsilon_0(i)]^2 + [\Gamma^{--}(\varepsilon)]^2} \right) \times [f(\varepsilon - eV - E_{\text{FR}}, T_{\text{L}}) - f(\varepsilon - E_{\text{FR}}, T_{\text{R}})], \quad (2)$$

$$I_{\uparrow\downarrow} = \frac{e}{h} \int_{E_{\text{FR}}}^{E_{\text{FR}}+eV} d\varepsilon \sum_i \left(\frac{4\Gamma_{\text{L}}^+(\varepsilon) \Gamma_{\text{R}}^-(\varepsilon)}{[\varepsilon - \varepsilon_0(i)]^2 + [\Gamma^{+-}(\varepsilon)]^2} + \frac{4\Gamma_{\text{L}}^-(\varepsilon) \Gamma_{\text{R}}^+(\varepsilon)}{[\varepsilon - \varepsilon_0(i)]^2 + [\Gamma^{-+}(\varepsilon)]^2} \right) \times [f(\varepsilon - eV - E_{\text{FR}}, T_{\text{L}}) - f(\varepsilon - E_{\text{FR}}, T_{\text{R}})], \quad (3)$$

where e is the elementary charge, $I_{\uparrow\uparrow}$ ($I_{\uparrow\downarrow}$) is the current flowing from right to left electrode when two Ni magnetic electrodes have parallel (antiparallel) magnetic moments, $T_{\text{L(R)}}$ is the temperature of left (right) electrode, $\Gamma^{++}(\varepsilon) = \Gamma_{\text{L}}^+(\varepsilon) + \Gamma_{\text{R}}^+(\varepsilon)$, $\Gamma^{--}(\varepsilon) = \Gamma_{\text{L}}^-(\varepsilon) + \Gamma_{\text{R}}^-(\varepsilon)$, $\Gamma^{+-}(\varepsilon) = \Gamma_{\text{L}}^+(\varepsilon) + \Gamma_{\text{R}}^-(\varepsilon)$, $\Gamma^{-+}(\varepsilon) = \Gamma_{\text{L}}^-(\varepsilon) + \Gamma_{\text{R}}^+(\varepsilon)$, and $f(\varepsilon, T) = 1/(\exp(\varepsilon/(k_{\text{B}}T)) + 1)$ is the Fermi-Dirac distribution function, where T is the temperature and k_{B} is Boltzmann's constant. Since both the electrodes are the same Ni, the equations $\Gamma^{+-}(\varepsilon) = \Gamma^{-+}(\varepsilon)$, $\Gamma_{\text{L}}^+(\varepsilon) = \Gamma_{\text{R}}^+(\varepsilon)$, $\Gamma_{\text{L}}^-(\varepsilon) = \Gamma_{\text{R}}^-(\varepsilon)$ hold from the symmetry. The superscript $+$ ($-$) designates the coupling between the density of states of the majority (minority) spin electrons and the molecule. Then, $\Gamma_{\text{L}}^+(\varepsilon)$, $\Gamma_{\text{R}}^+(\varepsilon)$ ($\Gamma_{\text{L}}^-(\varepsilon)$, $\Gamma_{\text{R}}^-(\varepsilon)$) are coupling strengths between the molecule and the majority (minority) spin electrons of left and right electrodes, respectively. Changing the temperature difference ΔT_{PC} of PCs, we have calculated the thermoelectric transport characteristics of SQCS devices at ambient temperature $T_{\text{a}} = 300$ K. In this case, we used the coupling strengths $\Gamma_{\text{L(R)}}^+(\varepsilon)$ of $47.2 \mu\text{eV}$ and $\Gamma_{\text{L(R)}}^-(\varepsilon)$ of $0.47 \mu\text{eV}$. Figures 2(a) and 2(b) show the calculated thermoelectric characteristics when two Ni electrodes have parallel magnetic moments, and when two Ni electrodes have antiparallel magnetic moments, respectively. From figures 2(a) and 2(b), we can notice that the thermoelectric voltage V_q changes from 0.48 mV to 2.12 mV with the temperature difference ΔT_{PC} of PCs increasing from 10 K to 50 K. Also, the magnitude of the thermoelectric voltage V_q is independent of spin directions and the thermopower S is $42.4 \mu\text{V/K}$ for both spin directions. On the other hand, the maximum power P_{max} extracted from PCs of SQCS devices is dependent on spin directions. The maximum power P_{max} can be computed from the I - V curve under the fourth quadrant. P_{max} 's are 5.14 pW, 0.105 pW at $\Delta T_{\text{PC}} = 50$ K for SQCS devices when two Ni electrodes have parallel and antiparallel magnetic moments, respectively. Therefore, we consider that PCs of SQCS devices can serve as spin dependent thermobatteries.

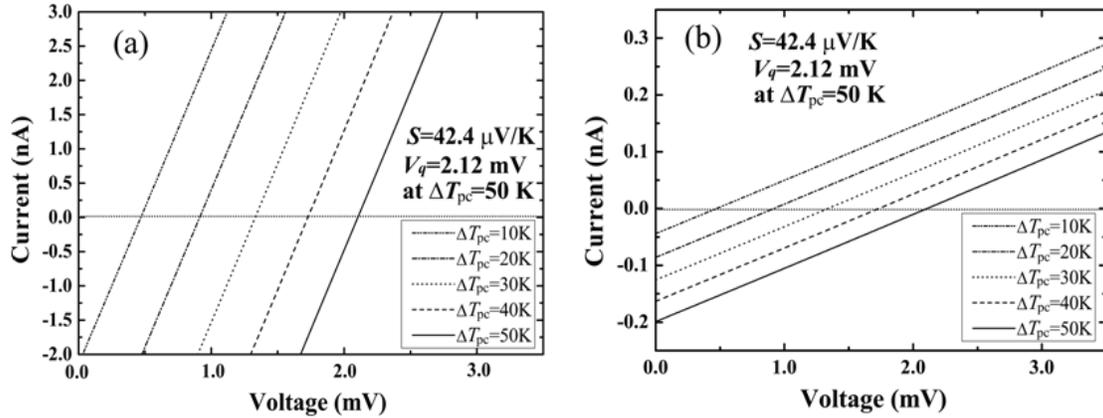

Figure 2. Thermoelectric transport characteristics of SQCS devices when two Ni electrodes have (a) parallel magnetic moments and (b) antiparallel magnetic moments.

We have realized an SQCS device with Ni thin film electrodes. Ni thin films have been thermally evaporated on polyethylene naphthalate (PEN) substrates (2 mm width, 10 mm length and 100 μm thickness) in a high vacuum chamber at a base pressure of 10^{-8} Torr. Fabricated Ni/PEN films have been sandwiched between two polymethyl methacrylate (PMMA) resins and the edge of PMMA/Ni/PEN/PMMA has been polished by chemical mechanical polishing (CMP) methods. Two sets of polished PMMA/Ni/PEN/PMMA have been prepared and attached together with their edges crossing. Figure 3(a) shows the schematic fabrication method of Ni SQCS devices. The evaporated Ni thin film is 2 mm wide, 10 mm long, and 17 nm thick. Figure 3(b) shows the experimental results of thermoelectric effects at PCs in Ni SQCS devices. The SQCS device was at room temperature 294.5 K at first. When the ambient temperature changes to 295.5 K, we notice that a large thermoelectric voltage V_q has emerged as shown in figure 3(b).

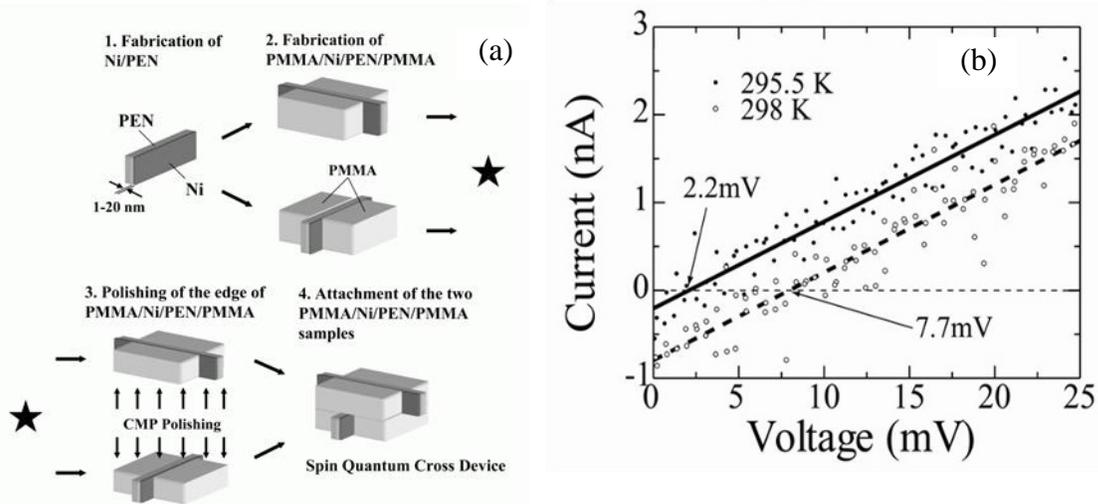

Figure 3. (a) Schematic fabrication method of Ni SQCS devices and (b) experimental results of thermoelectric effect of Ni SQCS devices.

Also, V_q changes from 2.2 mV to 7.7 mV when the ambient temperature changes from 295.5 K to 298 K. According to the above theory, the temperature at PCs of SQCS devices must be about

50 K in order to explain the result at 295.5 K. You may think that a temperature difference of 50 K is large. However, the difference can easily occur in the case that the thermal conductivities of the two electrodes differ from each other by one order of magnitude and that the process of heat transfer is transient. In this experiment, the thermal conductivity of one electrode is $\kappa_L=1.7 \times 10^{-2}$ W/cmK and that of the other electrode is $\kappa_R = 1.7 \times 10^{-3}$ W/cmK. The change in ambient temperature causes a thermal current between the two electrodes so that the temperature of the two electrodes approaches the ambient temperature. This process is much longer than expected, and it takes more than 15 minutes to reach equilibrium. The process can be regarded as transient during the I - V measurement. Figure 4(a) shows the calculated temperature difference between the Ni electrodes with different thermal conductivities by solving the one-dimensional thermal diffusion equation using the finite element method, assuming that only the edges of the electrodes are exposed to the ambient temperature. This approximation is very accurate because the other parts of the electrodes are covered with PMMA which is a heat insulating material. The coordinate systems for finite element method are shown in figure 4(b).

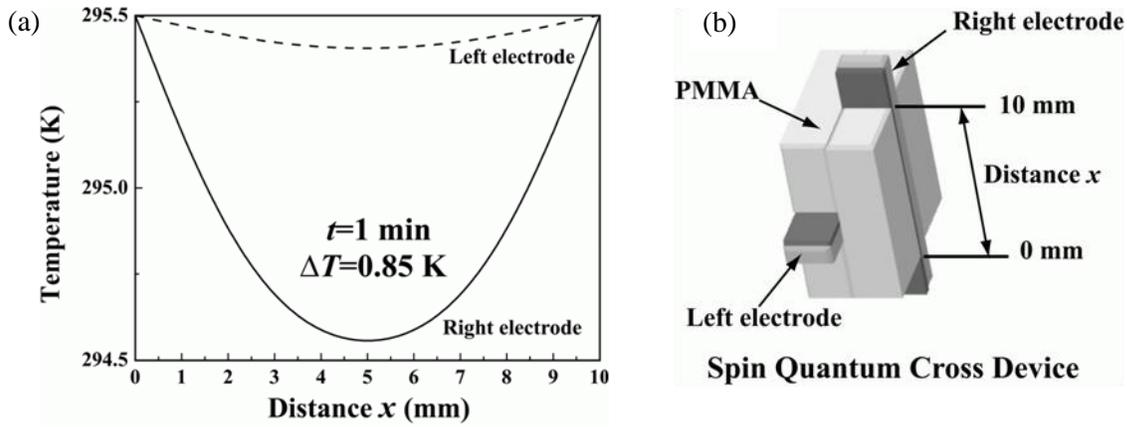

Figure 4. (a) Temperature difference between Ni electrodes with different thermal conductivities. (b) The coordinate systems for finite element method.

When the ambient temperature changes from 294.5 K to 295.5 K, the temperature of the left electrode with large thermal conductivity is almost 295.5 K after 1 minute. On the other hand, the temperature of the middle point (cross point) of the right electrode with small thermal conductivity remains almost unchanged even after 1 minute. Therefore, the temperature difference ΔT of 0.85 K arises at close proximity of the PC. As a result, a thermal flux is generated and flows into the PC of the SQCS device from the electrode. However, the thermal flux is disturbed at the PC of the device because the thermal conductance of the PC is as small as 6.58×10^{-11} W/K, which is estimated from the following equation:

$$\kappa_{PC} = L_0 G T_a (1 - S^2 / L_0), \quad (4)$$

where L_0 is the Lorentz number, and G is the conductance [10]. Therefore, a large temperature difference ΔT_{PC} at PC occurs in order to allow the same thermal flow through the PC as that through the electrodes, as shown in the following equation:

$$-\kappa_{PC} \Delta T_{PC} = J_t \approx -\kappa_L \Delta d \Delta T. \quad (5)$$

J_t is the thermal flow estimated at close proximity to the PC. Then, $\kappa_L \Delta d$ is the thermal conductance of the electrodes at close proximity of the PC, and we can ignore the thermal

conductance of the right electrode because its thermal conductance is smaller than that of the left electrode by one order of magnitude. If we assume that the gap Δd between the two Ni electrodes is 2.5 nm, we can estimate ΔT_{PC} to be 54.90 K at the PC. According to the above theory, the thermopower S is 42.4 $\mu\text{V}/\text{K}$. Then, V_q is 2.33 mV, which is in very good agreement with the experimental value of 2.2 mV. Using similar analysis, when the ambient temperature changes from 294.5 K to 298 K, the temperature difference ΔT of 2.97 K arises at close proximity of the PC. Therefore, we can estimate ΔT_{PC} to be 191.83 K at the PC. In this case, $V_q = S\Delta T_{PC}$ is 8.13 mV, which agrees very well with the experimental value of 7.7 mV. These very good agreements mean that the developed theory is very effective.

CONCLUSIONS

In this paper, we have investigated thermoelectric effects in point contacts (PCs) of Ni ferromagnetic metals using SQCS devices, which we have proposed as novel spintronics devices, theoretically and experimentally. The calculated results show that the thermoelectric voltage V_q changes from 0.48 mV to 2.12 mV with the temperature difference of PCs increasing from 10 K to 50 K. Also, the magnitude of the thermoelectric voltage V_q is independent of spin directions and the thermopower S is 42.4 $\mu\text{V}/\text{K}$ for both spin directions. On the other hand, the maximum power P_{max} extracted from PCs of SQCS devices is dependent on spin directions. Then, PCs of SQCS devices with Ni electrodes can serve as spin dependent thermobatteries. Also, we have measured thermoelectric effects in PCs of SQCS devices experimentally. The magnitude of the experimental thermoelectric voltage agrees very well with that of the theoretical result.
