(Received November 26, 2013; accepted September 3, 2014; published online November 11, 2014)

The Hubbard model in D dimensions, with the on-site repulsion \( U \) and the transfer integral between nearest neighbors \(-t/\sqrt{D}\), is studied on the basis of the Kondo-lattice theory. If \( U/|t| \gg 1 \), \( n-1 \lesssim |t|/(DU) \), where \( n \) is the number of electrons per unit cell, and \( D \) is so small that \( |J|/D \gg k_B T_c \), where \( J = -t^2/U \) and \( T_c \) is 0 K for \( D = 1 \) and is the highest critical temperature among possible ones for \( D \geq 2 \), a low-\( T \) phase where \( T_c < T < |J|/(k_B D) \) is a frustrated electron liquid. Since the liquid is stabilized by the Kondo effect in conjunction with the resonating-valence-bond (RVB) mechanism, it is simply the RVB electron liquid; in one dimension, it is also the Tomonaga-Luttinger liquid. The Kondo energy of the RVB liquid is \( k_B T_K = O(|J|/D) \); its effective Fermi energy is \( O(k_B T_K) \). A midband appears on the chemical potential between the upper and lower Hubbard bands; the Hubbard gap is a pseudogap. As regards the density of states per unit cell of the midband, its bandwidth is \( O(k_B T_K) \) or \( O(|J|/D) \), its peak height is \( O(1/U) \), and its spectral weight is \( O(|t|^2/(DU)^2) \). Since the midband almost disappears in the Heisenberg limit, the RVB electron liquid in the Heisenberg limit is simply the RVB spin liquid. The RVB electron and spin liquids adiabatically continue to each other. Since local moments form in a high-\( T \) phase where \( T \gtrsim T_K \), the high-\( T \) phase is simply the Mott insulator.

1. Introduction

A strong electron correlation is one of the most important issues in condensed-matter physics. The Hubbard model is one of the simplest effective Hamiltonians for studying the correlation. The Hubbard model in the Heisenberg limit is equivalent to the Heisenberg model. In the Heisenberg model on the triangular lattice, the resonating-valence-bond (RVB) mechanism is crucial for the stabilization of a frustrated spin liquid, in which no symmetry is broken; the frustrated spin liquid is simply the RVB spin liquid. The RVB mechanism is crucial for not only the triangular lattice but also other types of lattice in sufficiently low dimensions, and in not only the Heisenberg model but also the Hubbard model. If no symmetry is broken in a strongly correlated electron liquid, the electron liquid is frustrated, as the RVB spin liquid. If a frustrated electron liquid is stabilized by the RVB mechanism, it is simply an RVB electron liquid. It is interesting to study how crucial the RVB mechanism is for the stabilization of a frustrated electron liquid in low dimensions, particularly the Tomonaga-Luttinger (TL) liquid in one dimension.

The Hubbard model in one dimension is of particular interest, because no symmetry is broken in it, and the Bethe-ansatz solution is available for it. We consider the thermodynamic limit of \( N \to +\infty \) and \( L \to +\infty \), where \( N \) and \( L \) are the numbers of electrons and unit cells, respectively. According to the Bethe-ansatz solution, if the on-site repulsion \( U \) is nonzero once, a gap opens in the spectrum of a single-particle excitation in the half-filled ground state with \( N = L \); however, no gap opens in any non-half-filled ground state with \( N \neq L \). When \( T = 0 \) K, if and only if \( N = L \), a metal-insulator (MI) transition occurs at \( U = 0 \) as a function of \( U \). Since no symmetry is broken, the MI transition is never due to a broken symmetry. Lieb and Wu argue that the MI transition at \( U = 0 \) is the Mott transition. On the other hand, it is expected that the Mott transition will be possible only at a sufficiently large \( U \) such that \( U \) is as large as the bandwidth, or \( U = O(|t|) \), where \( |t| \) is the strength of the transfer integral between nearest neighbors, because it is due to the strong electron correlation.

If \( U/|t| \gg 1 \), the gap \( \epsilon_G(U) \) given by the Bethe-ansatz solution is as large as the Hubbard gap; however, \( \epsilon_G(U) = U - O(|t|) \). However, \( \epsilon_G(U) \) is so singular at \( U = 0 \) as a function of \( U \) that it cannot be expanded in terms of \( U \), as the ground-state energy. If \( U/|t| \ll 1 \), the gap is extremely small. It is doubtful whether the extremely small gap for \( U/|t| \ll 1 \) is the Hubbard gap. Therefore, it is doubtful whether the MI transition at \( U = 0 \) in one dimension is the Mott transition.

Unless \( U/|t| = +\infty \), the residual entropy per unit cell is zero or infinitesimal, depending on \( N \) and \( L \), in the thermodynamic limit; the third law of thermodynamics holds for any finite \( U/|t| \), even for the insulating ground state with \( N = L \). On the other hand, if \( U/|t| = +\infty \), the half-filled ground state is the prototype of the Mott insulator in not only one dimension but also higher dimensions; its residual entropy is \( k_B \ln 2 \) per unit cell. According to Brinkman-Rice theory, the Mott transition occurs at \( U_c = O(|t|) \) and the \( T \)-linear specific-heat coefficient diverges as \( U \to U_c \). If no symmetry is broken even for \( U \geq U_c \), the divergence means that the residual entropy per unit cell is nonzero for \( U \geq U_c \), or for the insulating ground state. In a previous paper, it is argued that if the ground state is the Mott insulator with no symmetry broken, the third law of thermodynamics is broken in it. In the present paper, the insulating ground state in one dimension is called Lieb and Wu’s insulator in order to distinguish it from the Mott insulator.

The number of electrons \( N \) is a natural variable in the canonical ensemble. If \( N = L \), the ground state is Lieb and Wu’s insulator; if \( N \neq L \), it is the TL liquid. On the other hand, the chemical potential \( \mu \) is a natural variable in the grand canonical ensemble. The average number of electrons per unit cell as a function of \( \mu \) is denoted by \( n(\mu) \); it corresponds to \( N/L \). The Bethe-ansatz solution is given for the Hubbard model on a bipartite lattice, which is symmetric under the particle-hole transformation for a particular chemical potential \( \mu_0 \); \( n(\mu_0) = 1 \) for any \( T \). If \( |\mu - \mu_0| < (1/2)\epsilon_G(U) \), it is expected that the ground state will be Lieb and Wu’s insu-
The present paper is an extension of previous study; 
sion theory, where Kondo-lattice theory (KLT) is a perturbative theory based on 
a chain, square, cubic, or hypercubic lattice:

2. Preliminary

2.1 Hubbard model

We consider the Hubbard model in D dimensions, i.e., on 
a chain, square, cubic, or hypercubic lattice:

\[ \mathcal{H} = \epsilon_d \sum \sigma n_{i\sigma} - \frac{t}{\sqrt{D}} \sum_{\langle i,j \rangle} d_{i\sigma}^\dagger d_{j\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow}, \]

(2.1)

where \( d_{i\sigma}^\dagger \) and \( d_{i\sigma} \) are the creation and annihilation operators of an electron with spin \( \sigma \) on the \( i \)th unit cell, \( n_{i\sigma} = d_{i\sigma}^\dagger d_{i\sigma} \), \( \epsilon_d \) is the band center, \(-t/\sqrt{D}\) is the transfer integral between nearest neighbors and \( t > 0 \) is assumed, \( \langle i,j \rangle \) stands for a pair of nearest neighbors, and \( U \) is the on-site repulsion. The number of unit cells is \( L \). The thermodynamic limit \( L \to +\infty \) is assumed. The periodic boundary condition is assumed. When \( U=0 \), the dispersion relation of an electron is given by

\[ E(k) = \epsilon_d - 2t \varphi_D(k), \]

(2.2)

where \( k = (k_1, k_2, \ldots, k_D) \) is the wave number, and

\[ \varphi_D(k) = \frac{1}{\sqrt{D}} \sum_{\nu=1}^D \cos(k_{\nu}a), \]

(2.3)

where \( a \) is the lattice constant. Because of the factor \( 1/\sqrt{D} \) in the transfer integral, the effective bandwidth of \( E(k) \) is \( O(|t|) \) for any \( D \); the absolute bandwidth is \( 4\sqrt{D}|t| \).

The number of electrons per unit cell is given by \( n(\mu) = \langle N / \rho \rangle / L \), where \( \rho = \sum_{\sigma} d_{i\sigma}^\dagger d_{i\sigma} \) and \( \langle \cdots \rangle \) stands for the thermal average in the grand canonical ensemble. If the chemical potential \( \mu \) lies at

\[ \mu_0 = \epsilon_d + (1/2)U, \]

(2.4)

the Hubbard model is symmetric and half-filled; \( n(\mu_0) = 1 \) for any \( T \).

2.2 Bethe-ansatz solution for one dimension

2.2.1 Effect of \( O(1/L) \) due to electron correlation

We consider one dimension. Since \( [\mathcal{H}, \hat{N}] = 0 \), a many-body eigenstate is specified by the number of electrons \( \hat{N} \), \( \mathcal{H} \hat{N} = \hat{N} \mathcal{H} \hat{N} \hat{N} \), and \( \mathcal{H} \hat{N} \alpha = E_{\alpha} \hat{N} \alpha \), where \( \alpha = \{ \cdots \} \) is a set of quantum numbers. In the thermodynamic limit, an infnite number of bosonic excitations, which do not change \( N \), are possible, so that many-body eigenvalues \( E_{\alpha \alpha} \) are continuously distributed in the range of

\[ E_{\alpha \alpha} \leq E_{\alpha \alpha} < +\infty, \]

(2.5)

where \( E_{\alpha \alpha} \) is the energy of the ground state or the ground-state multiplet, or \( \{ \alpha \} \). There is no upper limit for \( E_{\alpha \alpha} \).

Many-body eigenstates in the presence of a thermal and/or electron reservoir are more or less different from those in the absence of it. We assume that this difference can be ignored.

We assume that \( T = 0 \) K in the canonical ensemble. The retarded Green function in the site representation is given by

\[ R_{ij\sigma}(\epsilon + i0) = \frac{1}{v_N} \sum_{\bar{g}} R_{ij\sigma}(\epsilon + i0), \]

(2.6)

where the summation is over the ground-state multiplet and \( v_N \) is its degeneracy, and

\[ R_{ij\sigma}(\epsilon) = \frac{\langle \hat{N} \alpha | a_{i\sigma}^\dagger | (N + 1)\beta \rangle \langle (N + 1)\beta | a_{j\sigma}^\dagger | \hat{N} \alpha \rangle}{z - [E_{(N+1)\beta} - E_{\alpha \alpha}]} \]

\[ + \frac{\langle \hat{N} \alpha | a_{i\sigma}^\dagger | (N - 1)\beta \rangle \langle (N - 1)\beta | a_{j\sigma}^\dagger | \hat{N} \alpha \rangle}{z - [E_{\alpha \alpha} - E_{(N-1)\beta}]} \].

(2.7)

The site-diagonal Green function is given by

\[ R_{\sigma}(\epsilon + i0) = \frac{1}{v_N} \sum_{\bar{g}} \int_{-\infty}^{+\infty} d\epsilon' D_{\sigma}(\epsilon'), \]

(2.8)

\[ D_{\sigma}(\epsilon) = \sum_{\beta} \left| \langle (N+1)\beta | a_{i\sigma}^\dagger | \hat{N} \alpha \rangle \right|^2 \delta(\epsilon - E_{(N+1)\beta} + E_{\alpha \alpha}) \]

\[ + \sum_{\beta} \left| \langle (N-1)\beta | a_{i\sigma}^\dagger | \hat{N} \alpha \rangle \right|^2 \delta(\epsilon - E_{\alpha \alpha} + E_{(N-1)\beta}). \]

(2.9)

Neither \( R_{\sigma}(\epsilon + i0) \) nor \( D_{\sigma}(\epsilon) \) depends on the unit cell. The density of states per unit cell is given by

\[ \rho_N(\epsilon) = -\frac{1}{\pi} \text{Im} R_{\sigma}(\epsilon + i0) = \frac{1}{v_N} \sum_{\bar{g}} D_{\sigma}(\epsilon). \]

(2.10)

Two types of Fermi level are defined: \( \mu_+ \) for the addition of an electron and \( \mu_- \) for the removal of an electron. According to the Bethe-ansatz solution,\(^6\) if \( N \neq L \), \( [\mu_+(N) - \mu_-(N)] \to 0 \) as \( L \to +\infty \). No gap opens in \( \rho_{\pi \neq L}(\epsilon) \). The ground state is the TL liquid for any non-half filling.\(^3,4\) Either \( \rho_{N \neq L}(\epsilon) \) or
$D_{NL}(\epsilon)$ is more or less nonzero for any $\epsilon$.\(^{22}\)

On the other hand, if and only if $N = L$,

$$\epsilon_0(U) = \mu_+(L) - \mu_-(L) \quad (2.11)$$

is nonzero even in the limit $L \to +\infty$; $\mu_\pm(L) = \mu_0 \pm (1/2)\epsilon_0(U)$. Then, $\epsilon_0(U)$ is simply a gap in $D_L(\epsilon)$. The half-filled ground state is Lieb and Wu's insulator. It is easy to see that $p_L(\epsilon) = 0$ and $D_L(\epsilon) = 0$ for $|\epsilon - \mu_0| < (1/2)\epsilon_0(U)$. We define $\Delta E_{L0} = E_{L0} - E_{Lg}$. If $\Delta E_{L0} < (1/2)\epsilon_0(U)$, then $D_{L0}(\epsilon) = 0$ for $|\epsilon - \mu_0| < (1/2)\epsilon_0(U) - \Delta E_{L0}$, but $D_{L0}(\epsilon) > 0$ for $|\epsilon - \mu_0| \geq (1/2)\epsilon_0(U) - \Delta E_{L0}$. If $\Delta E_{L0} \geq (1/2)\epsilon_0(U)$, then $D_{L0}(\epsilon) > 0$ for any $\epsilon$. Thus, $D_{L0}(\epsilon) > 0$ at least for certain $\alpha$, regardless of $\epsilon$.

As a function of $N$, $\rho_N(\epsilon)$ is discontinuous between $N = L$ and $N = L \pm 1$, or between Lieb and Wu's insulator and the TL liquid. This discontinuous behavior is different from the continuous behavior between Wilson's band insulator and metal. The opening of $\epsilon_0(U)$ and the discontinuous behavior of $\rho_N(\epsilon)$ are different appearances of an effect due to the difference in electron correlation between $N = L$ and $N = L \pm 1$. The effect is an effect of $O(1/N)$ or $O(1/L)$ due to electron correlation.

2.2.2 Rigidity of Lieb and Wu's insulator

If many-body eigenstates of the Bethe-ansatz solution are used, the thermal Green function is given by

$$R_{i\sigma}(\epsilon \xi \ell) = \sum_{N_\alpha} p_{N\alpha}(T) R^{(N_\alpha)}_{i\sigma}(\epsilon \xi \ell + \mu) \quad (2.12)$$

where $\epsilon_\ell = (2l + 1)\pi k_B T$, with $l$ being an integer, $R^{(N_\alpha)}_{i\sigma}(\epsilon)$ is defined by Eq. (2.7), $\mu$ is the chemical potential, and

$$p_{N\alpha}(T) = \sum_{N'\alpha'} \exp[-(E_{N\alpha} - \mu N)/(k_B T)] \int \exp[-(E_{N'\alpha'} - \mu N')/(k_B T)]. \quad (2.13)$$

The site-diagonal thermal Green function is given by

$$R_{\sigma}(\epsilon \xi \ell) = \sum_{N_\alpha} p_{N\alpha}(T) \int_{-\infty}^{+\infty} d\epsilon' D_{N\alpha}(\epsilon' \xi \ell + \mu - \epsilon). \quad (2.14)$$

The density of states per unit cell is given by

$$\rho_\mu(\epsilon) = -\frac{1}{\pi} \text{Im} R_\sigma(\epsilon + i0) = \sum_{N_\alpha} p_{N\alpha}(T) D_{N\alpha}(\epsilon + \mu). \quad (2.15)$$

The average number of electrons per unit cell is given by

$$n(\mu) = \frac{1}{L} \sum_{N_\alpha} p_{N\alpha}(T) N = \int_{-\infty}^{+\infty} d\epsilon \frac{\rho_\mu(\epsilon)}{e^{\beta(\mu + \epsilon)} + 1}. \quad (2.16)$$

We assume that $|\mu - \mu_0| < (1/2)\epsilon_0(U)$. If $T = 0$ K,

$$\rho_\mu(\epsilon) = \rho_\mu(\mu + \epsilon). \quad (2.17)$$

Then, $\rho_\mu(\epsilon) = 0$ for $|\epsilon + \mu - \mu_0| < (1/2)\epsilon_0(U)$. The ground state is Lieb and Wu's insulator. It follows that

$$R_\sigma(\epsilon + i0) = -\frac{1}{\pi} \int_{-\infty}^{+\infty} d\epsilon' \rho_\mu(\mu + \epsilon') \frac{1}{e^{\beta(\mu + \epsilon') + i0}}. \quad (2.18)$$

Since $\rho_L(\epsilon)$ does not depend on $\mu$, neither $\rho_\mu(\epsilon - \mu)$ nor $R_\sigma(\epsilon - \mu + i0)$ depends on $\mu$. Lieb and Wu's insulator is rigid against the movement of $\mu$, as Wilson's band insulator. This is simply because many-body eigenstates in the absence of a reservoir are used and the reservoir effect is only implicitly treated through the statistical average or the probability function $p_{N\alpha}(T)$. The relevance of this treatment is critically examined in Sect. 5.2.

The static homogeneous charge susceptibility or the compressibility is given by

$$\chi_c(0, 0) = \frac{d\rho(\mu)}{d\mu}. \quad (2.19)$$

Because of the rigidity, $\chi_c(0, 0) = 0$ for $|\mu - \mu_0| < (1/2)\epsilon_0(U)$, or for Lieb and Wu's insulator.

2.2.3 Discontinuous MI transition at $T = 0$ K

We assume that $T = 0$ K in the grand canonical ensemble. An MI transition occurs at $\mu_\alpha = \mu_0 \pm (1/2)\epsilon_0(U)$ as a function of $\mu$. If $|\mu - \mu_0| < (1/2)\epsilon_0(U)$, the ground state is Lieb and Wu's insulator and no Fermi surface exists. Since no density wave appears, no folding of the Brillouin zone occurs. The absence of the Fermi surface means that its volume or size is absolutely zero in either the particle or hole picture.\(^{24}\) If $|\mu - \mu_0| > (1/2)\epsilon_0(U)$, the ground state is the TL liquid and the Fermi surface exists. According to the Fermi-surface sum rule,\(^{25, 26}\) the sizes of the Fermi surface are $2|k_B|\pi \alpha(n(\mu))$ and $2|k_B|\pi \alpha[n(\mu)/2 - n(\mu)]$ in the electron and hole pictures, respectively, where $k_B$ is the Fermi wave number in each picture. For example, if $\mu = \mu_0 + (1/2)\epsilon_0(U)$, the size of the Fermi surface is zero in either picture and $\rho_\mu(\epsilon) = 0$ for $-\epsilon_0(U) < \epsilon < 0$. If $\mu = \mu_0 + (1/2)\epsilon_0(U) + \epsilon$, the size of the Fermi surface is $2|k_B|\pi \alpha$ in either picture and $\rho_\mu(\epsilon) > 0$ even for $-\epsilon_0(U) < \epsilon < 0$. These discontinuous behaviors mean that the MI transition is discontinuous.

The compressibility $\chi_c(0, 0)$ is also discontinuous at $\mu_0 \pm (1/2)\epsilon_0(U)$ at least in the limit $U/|t| \to +\infty$, as studied below. As preliminary, we consider many-body eigenstates in the limit $U/|t| \to +\infty$. If $N \leq L$, no double occupancy at a unit cell is allowed. Every many-body eigenstate is specified by the set of $N$ pairs of wave number and spin, $(\{k\sigma\} = \{k_1\sigma_1, k_2\sigma_2, \cdots, k_N\sigma_N\})$. Its eigenfunction is the direct product of the charge part, which is a single Slater determinant of noninteracting $N$ spinless fermions, and the spin part, which is a product of spin functions of noninteracting $N$ spins:

$$\left| N\{k\sigma\} \right> = \sum_{\{x\}} \Phi_{\{k\sigma\}}(\{x\}) a_{x_1\sigma_1}^\dagger \cdots a_{x_N\sigma_N}^\dagger \left| 0 \right>. \quad (2.20)$$

$$\Phi_{\{k\sigma\}}(\{x\}) = \frac{1}{\sqrt{N!}} \prod_{p=1}^{N} \frac{1}{\sqrt{\sum_{x}} e^{ik_p x_s}} \sum_{x_1} N x_s(x_1), \quad (2.21)$$

where $|0\rangle$ is the vacuum where no electron exists, $\{x\} = \{(x_1, s_1), (x_2, s_2), \cdots, (x_N, s_N)\}$ with $0 \leq x_1 < x_2 < \cdots < x_N \leq L$ is the set of the position and spin coordinates of $N$ electrons, $P = (P_1, P_2, \cdots, P_N)$ is an $N$-permutation, $(-1)^P = 1$ for an even $P$ while $(-1)^P = -1$ for an odd $P$, and $x_s(x)$ is the spin function for $S = 1/2$. Its eigenenergy is given by $E_{\{k\sigma\}} = \sum_{p=1}^{N} E(k_p)$. If $N = L$, the spinless fermion band is completely filled and the electron state is the prototype of the Mott insulator. If $N \neq L$, the spinless fermion band is partially filled and the electron state is an exotic metal such that a complete charge-spin separation occurs in it and its ground-state degeneracy is $2^N$. If the hole picture is taken, a similar argument is possible for $N \geq L$.

We consider the limit $U/|t| \to +\infty$ in the grand canoni-
The self-energy in the site representation is defined by

$$R_{i\sigma}(i\vec{e}^t) = R_{i\sigma}^{(0)}(i\vec{e}^t) + \sum_{i'j'} R_{i'\sigma}^{(0)}(i\vec{e}^t)\Sigma_{i'j'\sigma}(i\vec{e}^t)R_{j'\sigma}(i\vec{e}^t),$$

(3.1)

where $\Sigma_{i\sigma}(i\vec{e}^t)$ is the self-energy and

$$R_{i\sigma}^{(0)}(i\vec{e}^t) = \frac{1}{L} \sum_{k} e^{i\hbar R_{i\sigma}(R_{i\sigma} - R_{j})} \frac{1}{i\vec{e}^t + \mu - E(k)}$$

(3.2)

is the Green function for $U = 0$; $R_{i}$ is the position of the $i$th unit cell. The self-energy $\Sigma_{i\sigma}(i\vec{e}^t)$ is decomposed into the single-site $\delta_{ij}\Sigma_{\sigma}(i\vec{e}^t)$ and the multisite $\Delta \Sigma_{ij\sigma}(i\vec{e}^t)$:

$$\Sigma_{i\sigma}(i\vec{e}^t) = \delta_{ij}\Sigma_{\sigma}(i\vec{e}^t) + \Delta \Sigma_{ij\sigma}(i\vec{e}^t).$$

(3.3)

The single-site $\Sigma_{\sigma}(i\vec{e}^t)$ does not depend on the unit cell.

The site-diagonal $R_{i\sigma}(i\vec{e}^t)$ and the single-site $\Sigma_{\sigma}(i\vec{e}^t)$ are local properties. It is possible to map them to their corresponding local properties of an appropriate impurity model. The appropriate impurity model is the Anderson model.18-20

We consider the Anderson model defined by

$$\tilde{H} = \bar{\epsilon}_d \sum_{i} n_{i\sigma} + \sum_{k\sigma} E_{c}(k)c_{k\sigma}^\dagger c_{k\sigma} + \tilde{U} n_{d1} n_{d1} + \frac{1}{L} \sum_{k\sigma} \left(V_{c} c_{k\sigma} d_{\sigma} + V_{c}^* d_{\sigma}^\dagger c_{k\sigma}\right),$$

(3.4)

where $n_{d\sigma} = d_{\sigma}^\dagger d_{\sigma}$, $\bar{\epsilon}_d$ is the level of $d$ electrons, $E_{c}(k)$ is the dispersion relation of conduction electrons, $\tilde{U}$ is the on-site repulsion, $L$ is the number of unit cells, and $V_{c}$ is the hybridization matrix between conduction and $d$ electrons. In the present paper, the temperature of the reservoir for the Anderson model is denoted by $T$ and treated as a parameter independent of $T$ for the Hubbard model. The Green function for $d$ electrons is given by

$$\tilde{G}_{\sigma}(i\vec{e}^t) = \frac{1}{i\vec{e}^t + \bar{\mu} - \bar{\epsilon}_d - \Sigma_{\sigma}(i\vec{e}^t) - \tilde{\Gamma}(i\vec{e}^t)},$$

(3.5)

$$\tilde{\Gamma}(i\vec{e}^t) = \frac{1}{\pi} \int_{-\infty}^{\infty} d\epsilon' \Delta(\epsilon') \tilde{\Gamma}(\epsilon) + \epsilon',$$

(3.6)

$$\Delta(\epsilon) = -\text{Im}\tilde{\Gamma}(\epsilon + i0) = \frac{1}{L} \sum_{k} \left|V_{c}\right|^2 \delta[\epsilon + \bar{\mu} - E_{c}(k)]$$

(3.7)

where $\bar{\epsilon}_d = (2l + 1)\pi k_{B}T$, with $l$ being an integer, and $\Sigma_{\sigma}(i\vec{e}^t)$ is the self-energy for $d$ electrons. The Anderson model is essentially uniquely characterized by the four parameters $T$, $\tilde{U}$, $\bar{\epsilon}_d - \bar{\mu}$, and $\Delta(\epsilon)$; none of the arbitrariness of $\bar{\epsilon}_d$, $\bar{\mu}$, $V_{c}$, or $E_{c}(k)$ is crucial. The four parameters have to be determined to satisfy an appropriate mapping condition.

Since $\Sigma_{\sigma}(i\vec{e}^t)$ is a local term, only $\tilde{U}$ and $\tilde{G}_{\sigma}(i\vec{e}^t)$ appear in any Feynman diagram for $\Sigma_{\sigma}(i\vec{e}^t)$ of the Anderson model; only $U$ and $R_{\sigma}(i\vec{e}^t)$ appear in any Feynman diagram for the single-site $\Sigma_{\sigma}(i\vec{e}^t)$ of the Hubbard model. Provided that

$$T = \tilde{T}, \quad U = \tilde{U},$$

(3.8a)

$$R_{\sigma}(i\vec{e}^t) = \tilde{G}_{\sigma}(i\vec{e}^t)$$

(3.8b)

are satisfied, it immediately follows that

$$\Sigma_{\sigma}(i\vec{e}^t) = \tilde{\Sigma}_{\sigma}(i\vec{e}^t).$$

(3.9)
Equation (3.8) is the appropriate mapping condition. At least
\[ \epsilon_d - \mu = \tilde{\epsilon}_d - \tilde{\mu}, \] (3.10)
has to be satisfied in order that Eq. (3.8b) can be satisfied. Then, it immediately follows that\(^{20}\)
\[ \Delta(\epsilon) = \Im \left[ \tilde{\Sigma}(\epsilon + i0^+) + 1/R_\sigma(\epsilon + i0^+)) \right]. \] (3.11)
If all of Eqs. (3.8a) and (3.10), and
\[ \Delta(\epsilon) = \Im [\Sigma(\epsilon + i0^+) + 1/R_\sigma(\epsilon + i0^+)] \] (3.12)
are satisfied, Eqs. (3.9) and (3.11) are satisfied. We can substitute Eq. (3.12) for Eq. (3.11). The set of Eqs. (3.8a), (3.10), and (3.12) is the mapping condition; Eq. (3.12) is a practical mapping condition because the others are simple.

It should be noted that \( \Delta(\epsilon) \) given by Eq. (3.12) depends on the temperature \( T \) of the reservoir for the Hubbard model. The mapped Anderson model itself includes \( T \) as a parameter.

There is no doubt on the possibility that, if the Hubbard model is solved once, the four parameters \( T, U, \tilde{\epsilon}_d - \tilde{\mu}, \) and \( \Delta(\epsilon) \) of the Anderson model can be uniquely determined from the mapping condition. All pairs of corresponding properties are exactly equal to each other between the Hubbard and Anderson models; e.g., \( \Sigma(\epsilon + i0^+) = \tilde{\Sigma}(\epsilon + i0^+), R_\sigma(\epsilon + i0^+) = \tilde{G}_\sigma(\epsilon + i0^+), \) \( \nu(\mu) = \tilde{n}(\tilde{\mu}), \rho_\mu(\tilde{\rho}(\epsilon), \) and so on, where \( \tilde{n}(\tilde{\mu}) = (n_{\uparrow \uparrow} + n_{\downarrow \downarrow}) \) and
\[ \tilde{\rho}(\epsilon) = -(1/\pi) \Im \tilde{G}_\sigma(\epsilon + i0^+). \] (3.13)
If \( \mu = \mu_0, \) the Anderson model is also symmetric.

The Green function for the Hubbard model in the wave-number representation is given by
\[ G_\sigma(\epsilon i\ell, k) = \frac{1}{L} \sum_{ij} e^{-ik \cdot (R_i - R_j)} R_{ij \sigma}(\epsilon i\ell), \]
\[ = \frac{1}{\epsilon i\ell + \mu - E(k) - \Sigma(\epsilon i\ell, k)}, \] (3.14)
Thus, \( \Sigma(\epsilon i\ell, k) = \Sigma(\epsilon i\ell) + \Delta \Sigma(\epsilon i\ell, k), \) (3.15)
\[ \Delta \Sigma(\epsilon i\ell, k) = \frac{1}{L} \sum_{ij} e^{-ik \cdot (R_i - R_j)} \Delta R_{ij \sigma}(\epsilon i\ell). \] (3.16)

Here, \( \Sigma(\epsilon i\ell, k), \Sigma(\epsilon i\ell), \) and \( \Delta \Sigma(\epsilon i\ell, k) \) are the total, single-site, and multisite self-energies, respectively.

The theory reviewed and reformulated above is KLT.\(^{18-21}\) Multisite terms have to be self-consistently considered with the Anderson model to be mapped. If no multisite term is considered in KLT, it is reduced to \( S^4 A \)\(^{14,16}\) Either the dynamical mean-field theory\(^{28,29}\) (DMFT) or the dynamical coherent-potential approximation\(^{30}\) (D CPA) is also \( S^4 A. \)

### 3.1.2. Nonzero and finite \( \Delta(\epsilon) \) of the Anderson model

The purpose of Sect. 3.1.2 is to show that if \( T > T_c, \)
\[ 0 < \Delta(\epsilon) < +\infty \] (3.17)
has to be satisfied in any self-consistent solution of KLT, in which \( \rho_\mu(\epsilon) > 0 \) is necessarily satisfied. We refer to a previous paper\(^{21}\) We define two real functions:
\[ Y_\mu(\epsilon) = \frac{1}{L} \sum_k \frac{S^2(\epsilon, k)}{S^2(\epsilon, k) + S^2(\epsilon, k)}, \] (3.18a)
\[ Z_\mu(\epsilon) = \frac{1}{L} \sum_k \frac{S^2(\epsilon, k)}{S^2(\epsilon, k) + S^2(\epsilon, k)}, \] (3.18b)
where \( S_1(\epsilon, k) = \Re [1/G_\sigma(\epsilon + i0^+, k)] \) and \( S_2(\epsilon, k) = \Im [1/G_\sigma(\epsilon + i0^+, k)]. \) It follows that
\[ Y_\sigma(\epsilon) = Z_\sigma(\epsilon), \] (3.19)
\[ R_\sigma(\epsilon + i0^+) = Y_1(\epsilon) - iZ_1(\epsilon), \] (3.20)
\[ Z_1(\epsilon) = \pi \rho_\mu(\epsilon) > 0, \] (3.21)
\[ Y_2(\epsilon) + Z_2(\epsilon) = 1. \] (3.22)
Since either of
\[ \frac{1}{L} \sum_k [x + S_1(\epsilon, k)]^2 = Y_0(\epsilon)x^2 + 2Y_1(\epsilon)xy + Y_2(\epsilon), \] (3.23a)
\[ \frac{1}{L} \sum_k [x + S_2(\epsilon, k)]^2 = Y_0(\epsilon)x^2 + 2Z_1(\epsilon)xy + Z_2(\epsilon), \] (3.23b)
cannot be negative for any real \( x, \)\(^{31}\) it follows that
\[ -Y_1^2(\epsilon) + Y_0(\epsilon)Y_2(\epsilon) \geq 0, \] (3.24a)
\[ -Z_1^2(\epsilon) + Z_0(\epsilon)Z_2(\epsilon) \geq 0. \] (3.24b)
The perturbative analysis in terms of \( U \) is useful for \( U/|t| \ll 1; \) that in terms of \( J = -4t^2/U \) based on KLT is useful for \( U/|t| \gg 1, \) as demonstrated in Sect. 4. In either analysis, it is easy to find terms that give a nonzero contribution to \( \Im \Sigma(\epsilon + i0^+) \) or \( \Im \Delta \Sigma(\epsilon + i0^+), \) provided that \( T > 0 K \) and \( \rho_\mu(\epsilon) > 0. \) If \( T > T_c, \) then \( \rho_\mu(\epsilon) > 0, \) so that
\[ 0 < -\Im \Sigma(\epsilon + i0^+) < -\Im \Delta \Sigma(\epsilon + i0^+). \] (3.25)
Then, \( Y_1(\epsilon) \) is finite and \( Z_1(\epsilon) \) is nonzero and finite, so that
\[ 0 < Y_1^2(\epsilon) + Z_1^2(\epsilon) < +\infty. \] (3.26)
First, we show that \( \Delta(\epsilon) \) cannot be positively divergent. If Eq. (3.20) is used, Eq. (3.12) can be described as
\[ \Delta(\epsilon) = \Im \Sigma(\epsilon + i0^+) + Z_1(\epsilon)/[Y_1^2(\epsilon) + Z_1^2(\epsilon)]. \] (3.27)
In general, \( \Im \Sigma(\epsilon + i0^+) \leq 0. \) According to Eq. (3.21) or (3.26), \( Z_1(\epsilon)/[Y_1^2(\epsilon) + Z_1^2(\epsilon)] < +\infty. \) Then, \( \Delta(\epsilon) < +\infty. \)
Next, we show that \( \Delta(\epsilon) \) has to be nonzero and positive. If Eq. (3.22) is used, Eq. (3.27) can be described as
\[ \Delta(\epsilon) = X(\epsilon)/[Y_1^2(\epsilon) + Z_1^2(\epsilon)], \] (3.28)
\[ X(\epsilon) = \Im \Sigma(\epsilon + i0^+) \left[ Y_1^2(\epsilon) + Z_1^2(\epsilon) \right] \]
\[ + Z_1(\epsilon) [Y_2(\epsilon) + Z_2(\epsilon)]. \] (3.29)
According to Eqs. (3.18b) and (3.25),
\[ Z_1(\epsilon) > -\Im \Sigma_\mu(\epsilon + i0^+) Z_0(\epsilon). \] (3.30)
According to Eqs. (3.19), (3.29), and (3.30),
\[ X(\epsilon) > -\Im \Sigma_\mu(\epsilon + i0^+) \left[ -Y_1^2(\epsilon) + Y_0(\epsilon)Y_2(\epsilon) \right] \]
\[ + \left[ -Z_1^2(\epsilon) + Z_0(\epsilon)Z_2(\epsilon) \right]. \] (3.31)
According to Eqs. (3.24), (3.25), and (3.31), it follows that \( X(\epsilon) > 0. \) According to \( X(\epsilon) > 0 \) and Eqs. (3.26) and (3.28), it follows that \( \Delta(\epsilon) > 0. \) Thus, Eq. (3.17) has to be satisfied.
Since $\Delta(\varepsilon) < +\infty$, $\hat{\Gamma}(\varepsilon + i0)$ can have no pole on the real axis in any self-consistent solution of KLT for $T > T_c$.

### 3.1.3 Polarization and vertex functions in the spin channel

Here, we refer to previous papers. The bosonic energy is denoted by $\omega_l = 2\pi k_B T$, with $l$ being an integer. In the wave-number representation, the irreducible polarization function $\pi_s(\omega_l, q)$ in the spin channel is decomposed into the single-site $\pi_s(\omega_l)$ and the multisite $\bar{\Delta}_s(\omega_l, q)$:

$$\pi_s(\omega_l, q) = \pi_s(\omega_l) + \bar{\Delta}_s(\omega_l, q).$$

The single-site $\pi_s(\omega_l)$ is equal to the local $\bar{\pi}_s(\omega_l)$ of the Anderson model: $\pi_s(\omega_l) = \bar{\pi}_s(\omega_l)$. The spin susceptibilities of the Anderson and Hubbard models are given by

$$\begin{align*}
\chi_s(\omega_l) &= 2\pi_s(\omega_l)/[1 - U\pi_s(\omega_l)], \quad \text{(3.33a)} \\
\chi_s(\omega_l, q) &= 2\pi_s(\omega_l, q)/[1 - U\pi_s(\omega_l, q)], \quad \text{(3.33b)}
\end{align*}$$

respectively. Here, the conventional factor $(1/4)\beta^2 \mu_B^2$ is not included, where $\beta$ is the inverse temperature. The susceptibility $\chi_s(\omega_l)$ of the Anderson model includes no contribution from the polarization of conduction electrons.

The kondo temperature or energy is defined by

$$\left[\tilde{\chi}_s(0; T)\right]_{T = 0 K} = 1/[k_B T_K(T)],$$

where $\tilde{T} = 0$ K means that the temperature of the reservoir for the Anderson model is the absolute zero Kelvin; $T$ of the reservoir for the Hubbard model or the parameter $T$ is explicitly shown because $\tilde{\chi}_s(0; T)$ and $T_K(T)$ depend on $T$. Although this definition of $T_K$ is different from Wilson’s by a numerical factor, $k_B T_K$ is still a measure of the magnitude of stabilization energy. Since $\hat{\rho}(\hat{\varepsilon}) = \rho_{\mu}(\varepsilon) > 0$ and $0 < \Delta(\varepsilon) < +\infty$ for $T > T_c$, $k_B T_K > 0$ and never $k_B T_K = 0$ in any self-consistent solution of KLT for $T > T_c$.

The formulation so far is valid for any finite $U/|t|$. The formulation in the following part is valid only for $U/|t| \gg 1$.

If $U/|t| \gg 1$, then $k_B T_K/|t| \ll 1$.

$$\tilde{\chi}_s(\omega_l) = 01/[k_B T_K],$$

for $T \lesssim T_K$ and $|\omega_l| \lesssim k_B T_K$. According to Eqs. (3.33) and (3.35), $U\pi_s(\omega_l) = 1 + O(k_B T_K/|t|)$, $U\pi_s(\omega_l, q) = 1 + O(k_B T_K/|t|)$, and $U^2 \bar{\Delta}_s(\omega_l, q) = O([k_B T_K/|t|]^2)$. Then,

$$U[1 - U\pi_s(\omega_l)] = 2\tilde{\chi}_s(\omega_l),$$

for $T \lesssim T_K$ and $|\omega_l| \lesssim k_B T_K$, where

$$I_s(\omega_l, q) = 2U^2 \bar{\Delta}_s(\omega_l, q)\tilde{\chi}_s(\omega_l).$$

Here, the terms of $O(k_B T_K/|t|)$ are ignored.

Equation (3.37) is consistent with the physical picture of Kondo lattices that local spin fluctuations interact with each other with an intersite exchange interaction; $I_s(\omega_l, q)$ is the intersite exchange interaction. The Neél temperature $T_N$ is determined from Eq. (3.37):

$$T_N = \max(T_s(\hat{q})),$$

where $T_s(\hat{q})$ as a function of $\hat{q}$ is defined by

$$[1 - (1/4)I_s(0, \hat{q})\tilde{\chi}_s(0)]_{T = T_s(\hat{q})} = 0.$$

According to the definition of $T_c$, if Eq. (3.39) gives $T_N$, $T_c \geq T_N$.

The reducible and irreducible three-point vertex functions in the spin channel are decomposed into single-site and multistate terms. The single-site terms can be mapped to the local vertex functions of the mapped Anderson model. If they are denoted by $\tilde{\lambda}_s(\omega_l, \hat{q}_l; \omega_l)$ and $\lambda_s(\omega_l, \hat{q}_l; \omega_l)$,

$$\tilde{\lambda}_s(\omega_l, \hat{q}_l; \omega_l) = \lambda_s(\omega_l, \hat{q}_l; \omega_l).$$

If Eq. (3.36) is used,

$$U\tilde{\lambda}_s(\omega_l, \hat{q}_l; \omega_l) = 2\tilde{\chi}_s(\omega_l)\tilde{\lambda}_s(\omega_l, \hat{q}_l; \omega_l).$$

### 3.2 Perturbation scheme to include multistate terms

### 3.2.1 Unperturbed state

In the Anderson model of Eq. (3.4), the Fermi surface of the conduction band is defined by $\tilde{\mu} = \varepsilon(\hat{K}_p)$, where $k_p$ is the Fermi wave number. According to Eq. (3.7), $\Delta(0) > 0$ is a sufficient condition for the existence of the Fermi surface. According to Eq. (3.17), the Fermi surface exists. Then, the ground state of the Anderson model is the normal Fermi liquid because of the Kondo effect. The normal Fermi liquid is characterized by nonzero $T_K(T)$, which depends on $T$ of the reservoir for the Hubbard model, or the parameter $T$. For convenience, $\tilde{T}$ of the reservoir for the Anderson model is treated as being independent of the parameter $T$, although eventually $\tilde{T} = T$ has to be assumed. In the following part, we assume that $0 K \lesssim \tilde{T} \lesssim T_K(T)$ and $T_c < T < \tilde{T} \lesssim T_K(T)$, and the parameter $T$ is explicitly shown.

We introduce an infinitesimal Zeeman energy into the Anderson model: $\mathcal{H}_Z = -\hbar(n_{l \uparrow} - n_{l \downarrow})$, where $\hbar = h^*$. The self-energy can be expanded in such a way that

$$\Sigma_\sigma(\varepsilon + i\varepsilon; T) = \Sigma_\sigma(0) + [1 - \tilde{\phi}(T)]\varepsilon + \sigma[1 - \tilde{\phi}(T)]\tilde{\varepsilon} + \cdots.$$
liquid\textsuperscript{23,26,36–38} If $\tilde{T} = 0$ K and no polarization of conduction electrons occurs, the static susceptibility of the Anderson model is given by

$$\tilde{\chi}_s(0; T) = 2\tilde{\phi}_s(T)\tilde{\rho}(0; T),$$  \hspace{1cm} (3.44)

where $\tilde{\rho}(0; T)$ is the density of states of the Anderson model. If $\Delta(\varepsilon; T)$ depends on $\varepsilon$, the polarization of conduction electrons occurs, in general; the static susceptibility of the Anderson model is approximately given by Eq. (3.44). Since $T_K(T)$ is defined by Eq. (3.34), it follows that

$$1/\tilde{\rho}(0; T) \simeq 2\tilde{\phi}_s(T)k_B T_K(T) \simeq 4\tilde{\phi}_1(T)k_B T_K(T).$$  \hspace{1cm} (3.45)

Since an electron liquid in the Hubbard model can be characterized by $\rho_0(0; T) = \tilde{\rho}(0; T)$, $\tilde{\phi}_1(0; T)$, and $k_B T_K(T)$, Eq. (3.45) is useful in the present paper.

The bosonic energy for $\tilde{T}$ is denoted by $\tilde{\omega}_l = 2\pi l T_K \tilde{T}$, with $l$ being an integer. According to the Ward relation,\textsuperscript{39}

$$\tilde{\chi}_s(i\tilde{\epsilon}_l, i\tilde{\epsilon}_l + i\tilde{\omega}_l'; i\tilde{\omega}_l; T) = 1 - \lim_{\hbar \to 0} \frac{d}{dh} \sum_{\sigma} \frac{\sigma}{2} \tilde{\Sigma}_\sigma(i\tilde{\epsilon}_l; T),$$  \hspace{1cm} (3.46)

for $\tilde{\omega}_l' = 0$. According to Eqs. (3.42) and (3.46),

$$\tilde{\chi}_s(i\tilde{\epsilon}_l, i\tilde{\epsilon}_l + i\tilde{\omega}_l'; i\tilde{\omega}_l; T) = \tilde{\phi}_s(T),$$  \hspace{1cm} (3.47)

for $\tilde{\omega}_l' = 0$ and $|\tilde{\epsilon}_l|/(k_B T_K) \rightarrow 0$. According to Eqs. (3.41) and (3.47),

$$U\tilde{\chi}_s(i\tilde{\epsilon}_l, i\tilde{\epsilon}_l + i\tilde{\omega}_l'; i\tilde{\omega}_l; T) = 2\tilde{\phi}_s(T)/\tilde{\chi}_s(i\tilde{\omega}_l; T),$$  \hspace{1cm} (3.48)

for $\tilde{\omega}_l' = 0$ and $|\tilde{\epsilon}_l|/(k_B T_K) \rightarrow 0$.

Every single-site property depends on the parameter $T$. If $T \leq T < T_K(T)$, the parameter $T$ dependence is so small that it can be ignored, except in the case of $D = 2$ and $\theta(\mu) \approx 1$, as discussed in Sect. 5.3. In the following part, $\tilde{T} = T$ is assumed, and the parameter $T$ is not shown.

If Eq. (3.42) is used, the Green function is given by

$$g_{\sigma}(i\tilde{\epsilon}_l, k) = \frac{1}{i\tilde{\epsilon}_l + \mu + \varepsilon_\sigma + \langle \tilde{E}(k) \rangle + \Delta \Sigma_\sigma(i\tilde{\epsilon}_l, k)}/\tilde{\phi}_1 - \tilde{\gamma}_K(i\tilde{\epsilon}_l).$$  \hspace{1cm} (3.49a)

Equation (3.49b) can also be described as

$$g_{\sigma}(i\tilde{\epsilon}_l, k) = g_{\sigma}^{(0)}(i\tilde{\epsilon}_l, k) + (1/\tilde{\phi}_1)\Delta \Sigma_\sigma(i\tilde{\epsilon}_l, k)g_{\sigma}(i\tilde{\epsilon}_l, k),$$  \hspace{1cm} (3.50)

for $|\tilde{\epsilon}_l| \gg k_B T_K$, where $\tilde{\gamma}_s(\mu, \tilde{h})$ is the number of localized electrons with spin $\sigma$ in the presence of the infinitesimal Zeeman energy $\tilde{h}$; in Eq. (3.53b), $\tilde{h}$'s in the denominators are ignored because they are not crucial. It follows that

$$\tilde{\chi}_s(0) = \lim_{\hbar \to 0} \frac{d}{dh} \left[ \tilde{\eta}_1(\tilde{h}, \tilde{\mu}) - \tilde{\eta}_1(\tilde{\mu}, \tilde{h}) \right].$$  \hspace{1cm} (3.54)

According to Eqs. (3.41), (3.46), (3.53), and (3.54),

$$U\tilde{\chi}_s(i\tilde{\epsilon}_l, i\tilde{\epsilon}_l + i\tilde{\omega}_l'; i\tilde{\omega}_l; T) = \frac{1}{\tilde{\chi}_s^{(0)}(i\tilde{\epsilon}_l)} \times \left( \frac{1}{i\tilde{\epsilon}_l + \mu - \varepsilon_d} + \frac{1}{i\tilde{\epsilon}_l + \mu + \varepsilon_d - \tilde{U}} \right),$$  \hspace{1cm} (3.55)

for $\tilde{\omega}_l' = 0$ and $|\tilde{\epsilon}_l| \gg k_B T_K$.

Since the superexchange interaction is a second-order effect in $-t/\sqrt{\tilde{D}}$, according to Eq. (3.38),

$$J_s(i\tilde{\omega}_l, q) = \frac{1}{T} \sum_{\langle ij \rangle} g^{(0)}(i\tilde{\epsilon}_l - R_i - R_j) J_{ij}(i\tilde{\omega}_l),$$  \hspace{1cm} (3.56)
If Eq. (3.48) is used, it follows that

$$J_{ij}(i\omega_n) = 2k_B T \sum_{\nu} U^2 \Delta^2_k \left( i\epsilon_{\nu} + i\omega_n \right) \left( -t/\sqrt{D} \right)^2 \times R_{ij}^2 \left( i\epsilon_{\nu} \right) R_{ij} \left( i\epsilon_{\nu} + i\omega_n \right).$$

(3.57)

If Eq. (3.53) is used for $R_{ij} \left( i\epsilon_{\nu} \right)$ and Eq. (3.55) is used for $U \Delta^2_k \left( i\epsilon_{\nu} + i\omega_n \right)$, its static part between nearest neighbors is given by $J_{ij}(0) = J/D$, where

$$J = -4t^2 \gamma U.$$  

(3.58)

This is simply given in previous papers, and is in agreement with that derived from the conventional theory. Since $J_{ij}(\omega + i0)$ is analytical in the upper-half complex plane, $J_{ij}(i\omega_n)$ can be generally described as

$$J_{ij}(i\omega_n) = \frac{J}{D} \int_0^{+\infty} dx X_f(x) \left( \frac{1}{i\omega_n + x} - \frac{1}{i\omega_n - x} \right),$$

(3.59)

where $X_f(x)$ satisfies

$$\int_0^{+\infty} dx X_f(x) \frac{1}{x} = \frac{1}{2}.$$  

(3.60)

Since $X_f(x)$ has a peak at $x \approx U$, it is assumed that $X_f(x) \approx (1/2U) d(x - U)$. Then,

$$J_{ij}(i\omega_n, q) = \frac{2J}{\sqrt{D}} \varphi_D(q) \frac{U}{2} \left( \frac{1}{i\omega_n + U} - \frac{1}{i\omega_n - U} \right),$$

(3.61)

where $\varphi_D(q)$ is defined by Eq. (2.3). In the static limit $|\omega_n|/U \rightarrow 0$, Eq. (3.61) is reduced to

$$J_{ij}(i\omega_n, q) = \frac{2J}{\sqrt{D}} \varphi_D(q) = \frac{2J}{D} \sum_{\nu=1}^{D} \cos(q\nu\alpha).$$

(3.62)

The superexchange interaction $J_{ij}(i\omega_n, q)$ is of higher order in $1/D$ for almost all $q$’s and is of the zeroth order in $1/D$ only for particular $q$’s, e.g., $q$’s on the line between $(\pi/a)(0, \pm 1, \cdots, \pm 1)$ and $(\pi/a)(\pm 1, \pm 1, \cdots, \pm 1)$.

3.2.3 Mutual interaction due to spin fluctuations

The mutual interaction due to spin fluctuations is given by

$$\Gamma_{\sigma}(i\omega_n, q; i\epsilon_{\nu}, i\epsilon_{\nu}) = U^2 \Delta_k \{ i\epsilon_{\nu} + i\omega_n \} \times \Delta_k \{ i\epsilon_{\nu} - i\omega_n \} \times \left[ \chi_k(i\omega_n, q) - \chi_k(i\omega_n) \right],$$

(3.63)

where $i\epsilon_{\nu}$ and $i\epsilon_{\nu}$ are the energies of incoming electrons, $i\epsilon_{\nu} + i\omega_n$ and $i\epsilon_{\nu} - i\omega_n$ are those of outgoing electrons, and $i\omega_n$ is the transfer energy. Since the single-site part is considered in the unperturbed state, it is subtracted in Eq. (3.63) in order to avoid double counting. It follows that

$$\chi_k(i\omega_n, q) - \chi_k(i\omega_n) = \left( 1/4 \right) \chi^2_k(i\omega_n) I^+_k(i\omega_n, q),$$

(3.64)

$$I^+_k(i\omega_n, q) = \frac{I_{\omega_n}(i\omega_n)}{1 - \left( 1/4 \right) I_k(i\omega_n, q) \chi_k(i\omega_n)}. $$

(3.65)

If Eq. (3.48) is used, it follows that

$$\Gamma_{\sigma}(i\omega_n, q; i\epsilon_{\nu}, i\epsilon_{\nu}) = \phi^2_k I^+_k(i\omega_n, q),$$

(3.66)

for $|\omega_n| \lesssim k_B T \xi$, $|i\epsilon_{\nu}| \lesssim k_B T \xi$, and $|i\epsilon_{\nu}| \lesssim k_B T \xi$. The single-site $\phi_k$ appears as a type of three-point vertex function.

If the mapped Anderson model is solved and the single-site $\tilde{\Sigma}_\sigma(i\epsilon_{\nu})$ and $\tilde{\chi}_k(i\omega_n)$ are given, the multisite $\Delta \Sigma_\sigma(i\epsilon_{\nu}, k)$ and $\Delta \pi(i\omega_n, q)$ can be perturbatively calculated in terms of the

4. RVB Liquid in Low Dimensions

4.1 RVB self-energy

We assume that

$$U/|t| \gg 1, \quad |n(\mu) - 1| \ll 1, \quad T_c < T < |J|/(k_B D).$$

(4.1)

We consider only the superexchange interaction $J_{ij}(i\omega_n, q)$ in the intersite $I_{\omega_n}(i\omega_n, q)$. There are two types of self-energy of the first order in $J_{ij}(i\omega_n, q)$: the Hartree-type and Fock-type self-energies. Since the Hartree-type self-energy is included in the conventional Hartree term, which is one of the single-site terms and is considered in the unperturbed state, it should not be considered in order to avoid double counting. The Fock-type self-energy is given by

$$\Delta \Sigma^{(\text{RVB})}_\sigma(i\epsilon_{\nu}, k) = \frac{k_B T}{L} \sum_{\nu=1}^{D} \frac{1}{\varphi_D(q\nu\alpha)} I_{\omega_n}(i\epsilon_{\nu} - i\epsilon_{\nu}, k - p),$$

(4.2)

where $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ is the Pauli matrix. What is considered for the Fock-type self-energy is simply the RVB mechanism. We call it the RVB self-energy.

If Eqs. (3.49) and (3.61) are used, it follows that

$$\Delta \Sigma^{(\text{RVB})}_\sigma(i\epsilon_{\nu}, k) = \frac{3}{4} \overline{W} \frac{J}{D} \Xi_D(i\epsilon_{\nu}) \varphi_D(k),$$

(4.3)

where $\overline{W}_k$ is the Wilson ratio, $J = -4t^2 / U$, and

$$\Xi_D(i\epsilon_{\nu}) = \frac{1}{L} \sum_{\nu} \varphi_D(p) \left\{ \frac{1}{2} U \left[ f_{-}(U) g_\sigma(i\epsilon_{\nu} + U, p) \right. \right.$$

$$\left. - f_{-}(U) g_\sigma(i\epsilon_{\nu} - U, p) \right\}$$

$$- \frac{1}{\pi} \int_{-\infty}^{+\infty} d\epsilon \left( 1/2 U \left[ \frac{1}{i\epsilon_{\nu} - \epsilon + U} - \frac{1}{i\epsilon_{\nu} + \epsilon - U} \right] \times \Im g_\sigma(\epsilon + i0, p) \right),$$

(4.4)

where $g_\sigma(\epsilon + i0, p)$ is given by Eq. (3.49b) and

$$f_{\pm}(\epsilon) = \frac{1}{e^{\epsilon/(k_B T)} + 1}.$$  

(4.5)

It is easy to confirm that

$$\lim_{|\epsilon| \rightarrow \infty} \Delta \Sigma^{(\text{RVB})}_\sigma(i\epsilon_{\nu}, k) = 0,$$

(4.6)

which is crucial to prove the sum rule in Appendix A. In the
If Eq. (3.62) is used instead of Eq. (3.61), Eq. (4.8) is simply given by

\[ \Delta \Sigma_\infty^{(\text{RBV})}(\varepsilon, \varepsilon) = \sum_i \frac{3}{4} \bar{W}_s^2 \bar{D} \Delta \Sigma_\infty^{(\text{RBV})}(\varepsilon, \varepsilon), \]  

(4.7)

If \(|\varepsilon_1|/U \ll 1\), Eq. (4.7) can be used for \(\Xi_D(\varepsilon)\) with sufficient accuracy. Then,

\[ \Delta \Sigma_\infty^{(\text{RBV})}(\varepsilon_1, \varepsilon) = \frac{3}{4} \bar{W}_s^2 J \bar{D} \Delta \Sigma_\infty^{(\text{RBV})}(\varepsilon, \varepsilon). \]

(4.8)

If Eq. (3.62) is used instead of Eq. (3.61), Eq. (4.8) is simply derived instead of Eq. (4.3).

4.2 Parameters characterizing the RBV liquid

If Eq. (4.8) is used, Eq. (3.49b) is simply given by

\[ g_0(\varepsilon_1, k) = \frac{1}{\varepsilon_1 + \mu^* - \varepsilon(k)} - \frac{1}{\varepsilon_1 + \mu^* - \varepsilon(k)} + \frac{1}{\varepsilon_1 + \mu^* - \varepsilon(k)}, \]

(4.9)

where \(\mu^*\) and \(\gamma_\infty(\varepsilon_1)\) are given by Eqs. (3.49c) and (3.49d), respectively.

\[ \xi(k) = -2t^* \Delta \Sigma_\infty^{(\text{RBV})}(\varepsilon_1, k), \]

(4.10)

\[ t^* = t\left(\frac{1}{\phi_1(0)} + 2c_f|t|/(DU)\right), \]

(4.11)

\[ c_f = \frac{3}{4}\bar{W}_s^2\Xi_D. \]

(4.12)

The density of states at the chemical potential is given by

\[ \rho_\mu(0) = -\frac{1}{\pi L} \sum_k \frac{1}{\phi_1(0)} \Im g_\mu(\varepsilon), \]

(4.13)

From Eqs. (3.45) and (4.13), it follows that

\[ k_B T_K = O(|t^*|). \]

(4.14)

Electrons in the midband can be described by \(\mu^*, t^*\) or \(k_B T_K\), \(\phi_1(0)\) and \(c_f\). In principle, they have to be self-consistently evaluated with each other as a function of \(T\) and \(\mu\) to satisfy the mapping condition given in Sect. 3.1.1. However, they can be approximately evaluated, as studied below.

According to the Fermi-surface sum rule, \(\sum_{\varepsilon_1 + \mu^* - \varepsilon(k)} = O\left(\frac{1}{\phi_1(0)}\right)\).

(4.15)

for \(T = 0\) K. If \(T = 0\) K and \(n(\mu) = 1\), then \(\mu^* = 0\), which is required by the particle-hole symmetry. Then, \(|\Xi_\varepsilon| = 1/\pi = 0.31831\ldots\), \(|\Xi_\infty| = 1/\pi = 0.28658\ldots\), and \(|\Xi_D| = 1/\pi = 0.283095\ldots\).

(4.16)

If \(|\Xi_D| = 1/3\) and \(\bar{W}_s = 2\) are assumed, then \(c_f = 1\).

The asymptotic behavior of \(1/\phi_1\) as \(U/t\) \(\to\) \(+\infty\) is studied in Appendix B: If \(n(\mu) = 1\), \(1/\phi_1 = O\left(\left|t^2/(DU^2)\right|\right)\), as shown in Eq. (B-11). According to Gutzwiller’s theory, \(\Delta(\varepsilon) = -\left[\Im \Sigma_\varepsilon(\varepsilon + i0)\right] + 1/\pi |\rho_\mu(\varepsilon)|\).

(4.17)

4.3 Possible types of electron liquid

If Eq. (4.1) is satisfied, the spectral weight of the midband, which is \(1/\phi_1\), is much smaller than unity, and the bandwidth of the midband, which is \(O(|t|^2)\), is much smaller than the bare bandwidth, which is \(O(|t|)\). We consider four typical cases of Eq. (4.1), where \(|t^2/(DU^2)| \ll 1|/(DU)\). First, we consider the case of

\[ |t^2/(DU^2)| \ll 1|/(DU) \ll |n(\mu) - 1|, \]

(4.18)

where \(n(\mu) \neq 1\) is assumed. According to Eq. (4.18) together with Eqs. (4.11), (4.13), (4.14), and (4.17),

\[ \rho_\mu(0) = O(1/|t|), \]

(4.19a)

\[ k_B T_K = O(|t| \cdot |n(\mu) - 1|). \]

(4.19b)

The single-site effect considered by Gutzwiller’s theory is more crucial than the RBV mechanism: \(\rho_\mu(0)\) weakly increases as \(U\) increase. If \(|t|/(DU) \ll |n(\mu) - 1|\), the electron liquid is simply given by Gutzwiller’s theory, which is under SSA, as will be discussed later in Sect. 5.1; thus, \(\rho_\mu(0)\) for such a large \(U\) is almost constant as a function of \(U\) and as large as that for \(U = 0\).

Second, we consider the case of

\[ |t^2/(DU^2)| \ll |n(\mu) - 1| \ll |t|/(DU), \]

(4.20)

where \(n(\mu) \neq 1\) is also assumed; \(U\) in this case is smaller than that considered in the first case, if \(n(\mu) \neq 1\) are the same as each other between the two cases. It follows that

\[ 1/\phi_1 = O\left(\left|n(\mu) - 1\right|\right), \]

(4.21a)

\[ O(1/U) < \rho_\mu(0) < O(1/|t|), \]

(4.21b)

\[ k_B T_K = O\left(\left|t^2/(DU^2)\right|\right) = O\left(|J|/D\right). \]

(4.21c)

The RBV mechanism is crucial and the electron liquid is the RBV liquid. Since the single-site effect becomes more and more relatively crucial to the RBV mechanism as \(U\) increases, \(\rho_\mu(0)\) increases as \(U\) increases.

Third, we consider the case of

\[ |n(\mu) - 1| \ll |t^2/(DU^2)| \ll |t|/(DU), \]

(4.22)

where \(n(\mu) \neq 1\) or \(n(\mu) = 1\) is assumed; if \(n(\mu) \neq 1\) are the same as each other between this case and the first or second case, \(U\) in this case is smaller than that considered in the first or second case. It follows that

\[ 1/\phi_1 = O\left(\left|t^2/(DU^2)\right|\right), \]

(4.23a)

\[ \rho_\mu(0) = O(1/U), \]

(4.23b)

\[ k_B T_K = O\left(\left|t^2/(DU^2)\right|\right) = O\left(|J|/D\right). \]

(4.23c)

The RBV mechanism is crucial and the electron liquid is a typical type of RBV liquid. The density of states \(\rho_\mu(0)\) becomes smaller as \(U\) increases. Particularly if \(n(\mu) = 1\), \(\rho_\mu(0) \to 0\) as \(U/t\) \(\to\) \(+\infty\). According to Eq. (3.12),

\[ \Delta(\varepsilon) = -\left[\Im \Sigma_\varepsilon(\varepsilon + i0)\right] + 1/\pi |\rho_\mu(\varepsilon)|, \]

(4.24)

for \(\varepsilon\) such that \(\text{Re} \Sigma_\varepsilon(\varepsilon + i0) = 0\). Since \(\text{Re} \Sigma_\varepsilon(\varepsilon + i0) = 0\) for \(\mu \neq 0\) and \(\text{Im} \Sigma_\varepsilon(\varepsilon + i0) \to 0\) as \(T \to 0\) K, \(\Delta(0) = O(U)\).

According to the considerations of the above three cases, the RBV mechanism is crucial, provided that

\[ |n(\mu) - 1| \ll |t|/(DU). \]

(4.25)
If \( n(\mu) \neq 1 \) is kept constant, \( \rho_\mu(0) \) is not a monotonous function of \( U \); \( \rho_\mu(0) \) as a function of \( U \) is minimal at approximately \( U \) such that \( n(\mu) - 1 = t^2/\langle D^2 \rangle \). If \( n(\mu) = 1, \rho_\mu(0) \) is a monotonous decreasing function of \( U \); \( \rho_\mu(U) \propto 1/U \).

Last, we consider a particular case of Eq. (4.22): the Heisenberg limit of \( U/|t| \to +\infty \) with \( J = -4t^2/|U| \) and \( n(\mu) = 1 \) kept constant. It follows that \( 1/\hat{\omega}_1 \to 0, \rho_\mu(0) \to 0, \) and \( \kappa_3 T_K = O(|J|/D) \). Although the bandwidth of the mid-band is nonzero and finite, either its spectral weight or density of states is infinitesimal. The RVB electron liquid in the Heisenberg limit is the most typical type of RVB electron liquid; it is a quasi-spin liquid, or simply the RVB spin liquid.

### 4.4 Metallic conductivity in the Heisenberg limit

We consider magnetic impurities:

\[
\mathcal{H}' = - \sum_{i,s,i' \sigma} J'_i \left( \sigma^{s,s'} \mathcal{S}' \right)^i \sigma^s d_i \sigma^s, \tag{4.26}
\]

where \( \mathcal{S}' \) is an impurity spin at the ith cell unit. We consider an ensemble for \( J'_i \) such that \( J'_i \) is positive, zero, or negative and is completely random from unit cell to unit cell and from sample to sample in the ensemble: \( \langle J'_i \rangle = 0, \langle J'_i J'_j \rangle = \delta_{ij} \langle J'_i^2 \rangle, \) \( \langle J'_i J'_j J'_k \rangle = 0, \) and so on, where \( \langle \cdot \cdot \cdot \rangle \) stands for the ensemble average. The translational symmetry is restored by the ensemble average. In the following part, the double-thermal-ensemble average is simply called an average.

Assuming that \( |J'_i| \ll \kappa_3 T_K \) for any \( i \), we treat impurity scattering in the Born approximation. The average self-energy \( \Sigma_\sigma(i\epsilon_l) \) due to the impurity scattering is given by self-consistently solving the following two equations:

\[
\Sigma_\sigma(i\epsilon_l) = \phi^2 \mathcal{S}(\mathcal{S}' + 1) \delta_{ij} \left\langle J'_i^2 \right\rangle \sum_k \frac{1}{\phi^2} \Sigma_\sigma(i\epsilon_j, k), \tag{4.27}
\]

\[
\Sigma_\sigma(i\epsilon_l, k) = \frac{1}{i\epsilon_l + \mu - \xi(k) - \gamma_\epsilon(i\epsilon_l) - (1/\phi^2) \Sigma_\sigma(i\epsilon_l, k)}, \tag{4.28}
\]

where \( \mathcal{S}' \) is the magnitude of impurity spins, \( \Sigma_\sigma(i\epsilon_l, k) \) is the average Green function multiplied by \( \phi^2 \), which corresponds to \( g_\sigma(i\epsilon_l, k) \) given by Eq. (3.49b) or (4.9), and \( \gamma_\epsilon(i\epsilon_l) \) is given by Eq. (3.49d). The average conductivity is given by

\[
\sigma_{xx}(\omega) = \frac{\hbar}{i\omega} \left\{ K_{xx}(\omega + i0) - K_{xx}(0) \right\}, \tag{4.29}
\]

where

\[
K_{xx}(i\omega_n) = \frac{1}{\Lambda^2} \int_0^\beta d\tau e^{i\omega_n \tau} \left\langle e^{i(\tau - \mu N)} j_x e^{-i(\tau - \mu N)} j_x \right\rangle, \tag{4.30}
\]

\[
\beta = \frac{1}{(k_B T)}, \quad j_x = -(e/h) \sum_{k} \langle \partial / \partial k_1 \rangle E(k) \tilde{n}_k, \quad \tilde{n}_k = (1/L) \sum_i \langle R_i \rangle e^{ik_1 R_i} d_i \sigma^s d_{i\sigma^s},
\]

\[
\Pi_{xx}(i\omega_n) = \frac{1}{L} \sum_{k p} \sum_{\sigma \sigma'} \text{sin}(k_1 a) \sin(p_1 a) \int_0^\beta d\tau e^{i\omega_n \tau} \left\langle e^{i(\tau - \mu N)} \tilde{n}_{k\sigma} e^{-i(\tau - \mu N)} \tilde{n}_{p\sigma'} \right\rangle. \tag{4.31}
\]

Here, \( \langle \cdot \cdot \cdot \rangle \) stands for the average. In order to satisfy the Ward relation, the ladder type of vertex correction due to the superexchange interaction has to be considered; the vertex correction due to the impurity scattering to be considered is also of the ladder type, but it vanishes. Then,

\[
\Pi_{xx}(i\omega_n) = \frac{1}{\phi^2} \frac{2\pi_{xx}(i\omega_n)}{1 + 3 \tilde{W}_s^2 J \pi_{xx}(i\omega_n)/(4D^2)}. \tag{4.32}
\]

where \( \tilde{W}_s \) is the Wilson ratio and

\[
\pi_{xx}(i\omega_n) = \frac{\kappa_3 T}{L} \sum_{nk} \text{sin}^2(k_1 a) \bar{g}(i\epsilon_1, k) \bar{g}(i\epsilon_1 + i\omega_n, k). \tag{4.33}
\]

The \( \omega \)-linear term of \( K_{xx}(\omega + i0) \) or \( \Pi_{xx}(\omega + i0) \) contributes to the static conductivity \( \sigma_{xx}(0) \). It follows that

\[
\frac{d\Pi_{xx}(i\omega_n)}{d(i\omega_n)} = \frac{(2/\phi^2) [d\pi_{xx}(i\omega_n)/d(i\omega_n)]}{[1 + 3 \tilde{W}_s^2 J \pi_{xx}(i\omega_n)/(4D^2)]^2}. \tag{4.34}
\]

If Eq. (4.36) is used, it is easy to show that

\[
\sigma_{xx}(0) = \frac{e^2}{\hbar^2} \left( 2/\phi_t^2 \right) S_{xx}(0), \tag{4.36}
\]

where \( S_{xx}(0) = (2h/\phi_t \) \( [d/d(\omega + i0) \pi_{xx}(\omega + i0)] \right|_{\omega=0}, \)

\[
S_{xx}(0) = 2h \pi \sum_k \text{sin}^2(k_1 a) \int_{-\infty}^{+\infty} \frac{d\epsilon}{|\epsilon|} \left[ \frac{f_x(\epsilon)}{d\epsilon} \right] \text{Im} \left[ \Sigma_\sigma(\epsilon + i0, k) \right]^2. \tag{4.37}
\]

If \( 2\text{sin}^2(k_1 a) = 1 - \cos(2k_1 a) \) is used and the term that includes \( \cos(2k_1 a) \) is ignored, it follows that

\[
\sigma_{xx}(0) = \frac{h}{2\pi} \int_{-\infty}^{+\infty} \frac{d\epsilon}{|\epsilon|} \left[ -\frac{f_x(\epsilon)}{d\epsilon} \right] \text{Im} \left[ \Sigma_\sigma(\epsilon + i0, k) \right]^2. \tag{4.38}
\]

We define two relaxation times, \( \gamma_\epsilon \) and \( \tau_\rho \), by

\[
\frac{h}{2\pi} = \int_{-\infty}^{+\infty} \frac{d\epsilon}{|\epsilon|} \text{Im} \left[ \frac{f_x(\epsilon)}{d\epsilon} \right] \left[ -\frac{f_x(\epsilon)}{d\epsilon} \right] \left[ \Sigma_\sigma(\epsilon + i0, k) \right]^2. \tag{4.39}
\]

\[
\frac{h}{2\pi} \gamma_\epsilon = \int_{-\infty}^{+\infty} \frac{d\epsilon}{|\epsilon|} \text{Im} \left[ \frac{f_x(\epsilon)}{d\epsilon} \right] \left[ \Sigma_\sigma(\epsilon + i0, k) \right]^2. \tag{4.40}
\]

respectively. If \( -i\hbar/(2\gamma_\epsilon) \) and \( -i\hbar/(2\tau_\rho) \) are used for \( \gamma_\epsilon(\epsilon + i0) \) and \( (1/\phi_t) \Sigma_\sigma(\epsilon + i0) \), respectively, and the energy dependence of \( \rho_\mu(E) \) is ignored in Eq. (4.38), it follows that

\[
\sigma_{xx}(0) = \frac{e^2}{\hbar^2} \left( 8/\phi_t^2 \right) \text{Im} \left[ \rho_\mu(0) \right]^2. \tag{4.41}
\]

Since \( \left| \tau^* \right| = O(|J|/D) \) and \( \phi_t (\rho_\mu(0) = O(1/|\tau^*|) \), \( \sigma_{xx}(0) \) is nonzero even in the limit \( 1/\phi_t \rightarrow 0 \); \( \rho_\mu(0) \rightarrow 0 \) in the limit \( 1/\phi_t \rightarrow 0 \). In an absolutely clean system, \( h / \tau_\rho \rightarrow 0 \). If no symmetry is broken or no complete gap opens even at \( T = +0 \text{ K} \) in the absolutely clean system, \( \sigma_{xx}(0) \) diverges as \( T \rightarrow 0 \text{ K} \) because \( 1/\gamma_\epsilon \rightarrow 0 \) as \( T \rightarrow 0 \). If the impurity scattering is sufficiently weak, the RVB electron liquid shows metallic conduc-
Adiabatic continuation

In the Heisenberg limit, the Hubbard model is reduced to

\[ \mathcal{H}_S = L_{ad} - \frac{1}{2D} \sum_{\langle i,j \rangle} (S_i \cdot S_j) = 2 \sum_i J'_i (S_i \cdot S'_i), \tag{4.42} \]

where the Hilbert space is constrained within the subspace where no empty or double occupancy is allowed, and \( S_i = (1/2) \sum_{\sigma \sigma'} \sigma \sigma' d_{i \sigma}^\dagger d_{i \sigma'} \). The last term in Eq. (4.42) is the impurity term given by Eq. (4.26). Since \( S_i \)'s satisfy the commutation relation for spin within the constrained Hilbert subspace, if the impurity term is excluded, \( \mathcal{H}_S \) is the Heisenberg model. The local gauge symmetry does not exist in the Hubbard model but exists in the Heisenberg model: \( [\mathcal{H}, n_{i1} + n_{i2}] \neq 0 \) and \( [\mathcal{H}_S, n_{i1} + n_{i2}] = 0 \) for any \( i \).

The role of the superexchange interaction is dual: the cause and suppression of magnetic instability. Since no suppression occurs in infinite dimensions, the mean-field approximation is rigorous for the Heisenberg model in infinite dimensions; the Néel temperature is as high as \( T_N \approx |J|/(2k_B) \) in not only the Heisenberg model but also the Heisenberg limit of the Hubbard model, as will be shown later in Eq. (5.15). The Néel temperature \( T_N \) is suppressed by two mechanisms: critical spin fluctuations and the RVB mechanism.\(^1\) The RVB mechanism stabilizes or prefers an unordered electron liquid in the Hubbard model and an unordered spin liquid in the Heisenberg model, rather than the Néel state. The stabilization energy due to the RVB mechanism is \( O(|J|/D) \) per pair of nearest neighbors or per unit cell; the RVB mechanism is \( O(1/D) \). If \( D \) is sufficiently small such that no \( T_N \) exists or, if it exists, \( T_N \ll |J|/(Dk_B) \), electron and spin liquids in the Hubbard and Heisenberg models at \( T \) such that \( T_N < T < |J|/(Dk_B) \) are the RVB electron and spin liquids, respectively.

The local gauge symmetry is a peculiar symmetry such that it cannot be spontaneously broken nor restored.\(^50\) In the reduction of the Hubbard model into the Heisenberg model, the local gauge symmetry is not spontaneously restored but is forced to be restored by constraining the Hilbert space within the subspace. The difference in the local gauge symmetry between two phases can never deny the possibility of the adiabatic continuation between them, as discussed below.

The relationship between the Hubbard and Heisenberg models is similar to that between the Anderson and s-d models. In the s-d model, the Anderson model is reduced to the s-d model. The local gauge symmetry does not exist in the Anderson model but exists in the s-d model. The density of states for d electrons can be defined in the Anderson model. If it is denoted by \( \rho(\varepsilon) \), \( \rho(\varepsilon) > 0 \) at least for a sufficiently small \( \varepsilon \), which means that low-energy single-particle excitations are possible, as in the Hubbard model. On the other hand, \( \rho(\varepsilon) \) cannot be defined in the s-d model, which means that no single-particle excitation is possible, as in the Heisenberg model. On the other hand, according to Nozières’ theory,\(^51\) it is possible to describe the spin liquid in the s-d model as the normal Fermi liquid. The Fermi-liquid theory for the spin liquid in the s-d model is exactly equivalent to that for the Fermi liquid in the Anderson model in the s-d limit.\(^36,37\) Thus, the spin liquid in the s-d model adiabatically continues to the Fermi liquid in the Anderson model.

The conductivity of the RVB spin liquid is zero, but that of the RVB electron liquid can be divergent at \( T = 0 \) K even in the Heisenberg limit if no impurity exists and no symmetry is broken even at \( T = 0 \) K, as studied in Sect. 4.4. This extreme difference in the conductivity cannot exclude the possibility of the adiabatic continuation between the RVB spin and electron liquids either, as discussed below.

The strength of magnetic impurities can be used as an adiabatic parameter. Here, it is assumed that \( -\infty < J'_i < +\infty \) and \( 0 < \| J'_i \|^2 < +\infty \). Clean and dirty limits are defined by the limit \( \| J'_i \|^2 \to 0 \) and the limit \( \| J'_i \|^2 \to +\infty \), respectively. In the dirty-limit Hubbard model, an electron is localized almost within a unit cell, so that the local gauge symmetry is almost restored and the conductivity is almost zero. It is certain that every physical property of the dirty-limit Hubbard model in the Heisenberg limit is the same as that of the dirty-limit Heisenberg model. Thus, the electron state in the dirty-limit Hubbard model in the Heisenberg limit and the spin state in the dirty-limit Heisenberg model adiabatically continue to each other.

According to the scaling theory for the Anderson localization,\(^49\) there is no critical point between the metallic and insulating phases, or between the itinerant and localized states, or between the clean and dirty limits; there is also no lower limit of the metallic conductivity or minimum metallic conductivity.

There is no critical point between the metallic and insulating phases, or between the itinerant and localized states, or between the clean and dirty limits; there is also no lower limit of the metallic conductivity or minimum metallic conductivity. Therefore, the RVB electron liquid in the clean-limit Hubbard model adiabatically continues to the electron state in the dirty-limit Hubbard model. It is obvious that the RVB spin liquid in the clean-limit Heisenberg model adiabatically continues to the spin state in the dirty-limit Heisenberg model. Thus, the RVB electron liquid in the clean-limit Hubbard model and the RVB spin liquid in the clean-limit Heisenberg model adiabatically continue to each other.

5. Discussion

5.1 Nature of the Mott insulator

Either the Mott insulator or Lieb and Wu’s insulator competes with the RVB liquid. It is desirable to examine its nature in order to confirm that the RVB liquid is stable against it. Here, we examine the nature of the Mott insulator. We assume that \( U/|t| \gg 1 \) and \( \mu = \mu_0 \), unless otherwise noted.

If \( T > T_c \), no symmetry is broken. The Kondo energy \( k_B T_K \) is the energy scale of quantum spin fluctuations in the RVB liquid as well as a measure of its stabilization energy: \( k_B T_K = O(|t|^2/(DU)) \).\(^52\) We assume that \( D \) is so small that \( T_c \ll T_K \). If \( T \) is so low that \( T \ll T_K \), quantum spin fluctuations are more dominant than thermal spin fluctuations, the entropy is small, and electrons are itinerant. The RVB liquid is stabilized in the low-T phase of \( T \ll T_K \) in sufficiently low dimensions. If \( T \) is so high that \( T \gg T_K \), thermal spin fluctuations are more dominant than quantum spin fluctuations, the entropy is as large as \( k_B \ln 2 \) per unit cell, and electrons behave as local moments. Since the high-T phase where \( T \gg T_K \) behaves as an insulator, it is simply the Mott insulator. An MI transition or crossover occurs at \( T \approx T_K \) as a function of \( T \) between the RVB liquid and the Mott insulator. Then, a high-T phase where \( T \gg T_K \), rather than \( T \gg T_K \), is
also the Mott insulator. If $D$ is so large that $T_c \geq T_K$, a high-$T$ phase where $T > T_c$ is the Mott insulator because $T_0 \geq T_K$. The Mott insulator is stabilized as a high-$T$ phase with a large entropy in low or high dimensions, while the RVB liquid is stabilized as a low-$T$ phase with a small entropy only in sufficiently low dimensions. The Mott insulator and the RVB liquid never contradict each other.

If $T < T_c$, the symmetry is broken, except for one dimension. If $T_c \geq T_K$, not only the Néel state but also the type of insulator proposed by Slater is possible below $T_c$ in a multiband model, as will be discussed later in Sect. 5.5.

Since the RVB mechanism is a multisite effect, it never appears under $S^3A$; it is expected that $k_B T_K = 0$ will be possible for $U/|t| > 1$. Since any type of the conventional Weiss mean field is also a multisite effect, it never appears under $S^3A$; no symmetry can be broken. It is expected that the Mott insulator, which is a high-$T$ phase with a large entropy, will be possible even at $T = 0$ K under $S^3A$.

According to a numerical study based on DMFT or $S^3A$, the Mott insulator is possible even at $T = 0$ K. An MI transition with hysteresis occurs below the critical temperature $T_c$. The hysteresis is characterized by two transition lines of $U_{c1}(T)$ and $U_{c2}(T)$ in the $T-U$ phase diagram. The model used in the numerical study is different from that used in the present study. If the absolute bandwidth is denoted by $W$, $U_{c1}(T) \approx W$, $U_{c2}(T) \approx W$, and $U_{c1}(T) < U_{c2}(T)$ for $T > T_0$; $U_{c1}(T_K) = U_{c2}(T_K)$. When $U$ increases, an MI transition occurs at $U = U_{c2}(T)$; when $U$ decreases, it occurs at $U = U_{c1}(T)$. The insulating phase at $T = 0$ K for $U \geq U_{c1}(0)$ K or $U \geq U_{c2}(0)$ K, depending on the decreasing or increasing process of $U$, is a typical type of the Mott insulator, i.e., the Mott insulator in which a complete gap opens.

According to our previous paper, either under or beyond $S^3A$, a complete gap opens if and only if $\Sigma_\sigma(e+i0)$ and/or $\tilde{\Gamma}(e+i0)$ of the Anderson model has a pole at $e = 0$; when $\mu = \mu_0$, e.g., a gap as large as $e_0$ opens if and only if

$$\Sigma_\sigma(e+i0) = \frac{U}{2} \frac{|\lambda_{c1}|}{e+i0} - \frac{1}{\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{\text{Im} \Sigma_\sigma(e+i0)}{e+i0},$$

(5.1a)

$$\tilde{\Gamma}(e+i0) = \frac{|\lambda_{c2}|}{e+i0} - \frac{1}{\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{\text{Im} \tilde{\Gamma}(e+i0)}{e+i0},$$

(5.1b)

with $|\lambda_{c1}| > 0$ or $|\lambda_{c2}| > 0$, are satisfied. If $\Sigma_\sigma(e+i0)$ has a pole at $e = 0$, $k_BT_K = 0$ and the residual entropy of the Hubbard model is $k_BT_K = 2$ per unit cell. If $\lambda_{c1} = 0$ and $|\lambda_{c2}| > 0$, or if only $\tilde{\Gamma}(e+i0)$ has a pole at $e = 0$, the residual entropy is zero; the argument in our previous paper that if $|\lambda_{c2}| > 0$ then $|\lambda_{c1}|$ has to be nonzero is irrelevant.

Since $\tilde{\Gamma}(e+i0)$ can have no pole at $e = 0$ under $S^3A$, $\Sigma_\sigma(e+i0)$ has to have a pole at $e = 0$ for the Mott insulator at $T = 0$ K. Then, $k_BT_K = 0$ and the residual entropy is $k_B \ln 2$ per unit cell, i.e., the third law of thermodynamics is broken.

The Mott insulator at $T = 0$ K has to be regarded as a high-$T$ phase rather than a low-$T$ phase. Either under or beyond $S^3A$, the Mott insulator can be stabilized only as a high-$T$ phase with a large entropy but can never be stabilized as a low-$T$ phase with a small entropy, even if it is stabilized at $T = 0$ K.

If symmetry breaking is ignored, it is easy to extend the analysis based on KLT to $T \leq T_c$, except for $T = 0$ K. If $T > 0$ K, $\rho_\mu(e) > 0$ even if the ground state is an insulator. Then, $k_BT_K = O[2/(DU)]$. If $T > T_K$, the Mott insulator is stabilized; if $0 < K < T < T_K$, the RVB liquid is stabilized. An MI transition or crossover occurs at $T \approx T_K$ as a function of $T$ between them. The analysis for $T > 0$ K never denies the possibility that $\rho_\mu(0) = 0$ for $T = 0$ K, i.e., the ground state is an insulator.

Since no higher-order term in $1/D$ is included in $S^3A$, strictly speaking, it is not a theory for $1/D \to 0$ but a theory for exactly $1/D = 0$. It should be determined whether, if symmetry breaking is ignored, $S^3A$ is equivalent to KLT in the limit $1/D \to 0$ and rigorous in the limit $1/D \to 0$.

Beyond $S^3A$, or in KLT, $k_BT_K = O[2/(DU)]$ is more or less nonzero. In the limit of $1/D \to 0$ followed by $T \to 0$ K, $T \to T_K$ and the Mott insulator is stabilized; the numerical study based on DMFT or $S^3A$ is consistent with KLT. In the limit of $T \to 0$ K followed by $1/D \to 0$, $T \to T_K$ and the RVB liquid is stabilized; the numerical study is inconsistent with KLT. The inconsistency means or implies that $S^3A$ is not rigorous in the limit $1/D \to 0$.

In the limit $U/|t| \to 0$, if $T$ is so low that $k_BT < |t|$, a metal is stabilized, because $k_BT_K = O(\epsilon)$. If $T < T_K$, the Mott insulator is stabilized, because $k_BT_K = O[2/(DU)] \to 0$ as $U/|t| \to +\infty$ and $T \to T_K$. If $T$ is nonzero and sufficiently low such that $0 < k_BT < |t|$, an MI crossover or transition occurs as a function of $U$. Since $k_BT_K = O[2/(DU)]$ is nonzero for any $|t|/U > 0$ unless $1/D = 0$, it is expected that no transition but only a crossover will occur beyond $S^3A$. If this expectation is true, the transition in the numerical study based on DMFT is inconsistent with the crossover beyond $S^3A$. Against the expectation, we assume that a transition is possible at a sufficiently low $T$ beyond $S^3A$. We consider the model used in the numerical study; its absolute bandwidth, which is finite, is also denoted by $W$, as in the discussion above. The Kondo energy is given by $k_BT_K = O[2/(DU)]$ in the limit $T \to 0$ K. Since no transition is possible as a function of $T$ at least in the limit $U/W \to 0$, a critical point has to exist in the $T-U$ phase diagram. If hysteresis exists, $U_{c1}(0 + 0 K) < U_{c2}(0 + 0 K)$; if not, $U_{c1}(0 + 0 K) = U_{c2}(0 + 0 K)$. Since $k_BT_K = O[2/(DU)]$ is more or less nonzero for any $W/U > 0$ unless $1/D = 0$, $U_{c2}(T) \to +\infty$ as $T \to 0$ K for any finite $D$; i.e., at least $U_{c2}(0 + 0 K)$ is infinite beyond $S^3A$, regardless of whether hysteresis exists or not. In the numerical study, on the other hand, hysteresis appears and either $U_{c1}(0 K)$ or $U_{c2}(0 K)$ is finite and $O(W)$, as discussed above. The finite $U_{c2}(D)$ or $U_{c2}(0 K)$ in the numerical study is inconsistent with the infinite $U_{c2}(0 K)$ beyond $S^3A$. The $T-U$ phase diagram of the numerical study is inconsistent with that beyond $S^3A$, regardless of whether an MI crossover or transition occurs beyond $S^3A$. This finding also means or implies that $S^3A$ is not rigorous even in the limit $1/D \to 0$.

We consider an electron state in the limit $T \to 0$ K, never at $T = 0$ K. If $k_BT_K > 0$, the electron state is a metal. Thus, $\text{Im} \Sigma_\sigma(+i0, k) \to 0$ as $T \to 0$ K. Then,

$$\rho_\mu(0) = \frac{1}{L} \sum_k \delta [\mu - (E(k) - \text{Re} \Sigma_\sigma(+i0, k)],$$

(5.2a)
and, according to the Fermi-surface sum rule,\textsuperscript{25,26}

\[
n(\mu) = \frac{1}{L} \sum_{k} \theta \left[ \mu - E(k) - \text{Re} \Sigma_{\sigma} (+i0, k) \right],
\]

(5.2b)

where \( \theta(x) = (1 + x/|x|)/2 \). Under \( \text{S}^3 \text{A} \) or SSA, the self-energy \( \Sigma_{\sigma}(+i0, k) \) does not depend on \( k \). It is easy to show that \( \rho_{\sigma}(0) \) is constant as a function of \( U \) if \( n(\mu) \) is kept constant; \( \rho_{\sigma}(0) \) is simply given by that for \( U = 0 \). The constant \( \rho_{\sigma}(0) \) as a function of \( U \) is a property peculiar to the metallic phase under SSA. If the Mott transition occurs, the decrease in \( \rho_{\sigma}(0) \) with increasing \( U \) is necessarily discontinuous from the constant \( \rho_{\sigma}(0) \) of the metal to the zero \( \rho_{\sigma}(0) \) of the Mott insulator. On the other hand, if the RVB mechanism is considered and if Eq. (B-11) or \( 1/\delta_{1} = O[(T/|DU|)] \) is used, \( \Delta \Sigma_{\text{RVB}}(+i0, k) \propto (1/D)^{0}U_{P}D(k) \text{,} \quad \text{if } U/|t| \gg 1 \), the dispersion of \( E(k) \) can be ignored in Eq. (5.2). Then, \( \rho_{\sigma}(0) = O(1/U) \) for \( \mu = \mu_{0} \) or \( n(\mu) = 1 \). The continuous decrease in \( \rho_{\sigma}(0) \) with increasing \( U \) is a property peculiar to the RVB liquid with the half filling. The inconsistency in the \( U \) dependence of \( \rho_{\sigma}(0) \) between under and beyond \( \text{S}^3 \text{A} \) also means or implies that \( \text{S}^3 \text{A} \) is not rigorous even in the limit \( 1/D \rightarrow 0 \).

Any of the three inconsistencies discussed above between the numerical study\textsuperscript{24} and the present paper is simply because the RVB mechanism cannot be considered under \( \text{S}^3 \text{A} \) but can be considered beyond \( \text{S}^3 \text{A} \). Beyond \( \text{S}^3 \text{A} \), \( k_{B}T_{K} = O[(T/|DU|)] \) is nonzero. If the Mott insulator in which a completely opens, which is characterized by \( k_{B}T_{K} = 0 \), is possible at \( T = 0 \ K \) under \( \text{S}^3 \text{A} \), \( \text{S}^3 \text{A} \) is not necessarily equivalent to KLT in the limit \( 1/D \rightarrow 0 \) nor necessarily rigorous in the limit \( 1/D \rightarrow 0 \). The rigorousness of \( \text{S}^3 \text{A} \) in the limit \( 1/D \rightarrow 0 \) is examined in Appendix D.

5.2 Nature of Lieb and Wu’s insulator

If the fact that \( \rho_{\sigma}(0) > 0 \) for \( T > 0 \ K \) is seriously considered, the RVB-TL liquid is stabilized in the low-\( T \) phase of \( 0 \ K < T < |J|/k_{B} \) in one dimension; the possibility is not denied that \( \rho_{\sigma}(0) = 0 \) for \( T = 0 \ K \), i.e., the ground state is an insulator.\textsuperscript{54} According to the treatment in Sect. 2.2.2, the ground state for \( |\mu - \mu_{0}| < (1/2)e_{0}(U) \) in the grand canonical ensemble is simply Lieb and Wu’s insulator itself, which is given by the Bethe-ansatz solution for the canonical ensemble. Here, we examine the nature of this insulator. We assume that \( D = 1 \), \( T = 0 \ K \), and \( U/|t| \gg 1 \), unless otherwise noted.

If the Bethe-ansatz solution is used, it is possible to determine all the physical properties in the grand canonical ensemble with essentially the same treatment as that in Sect. 2.2.2, in principle; then, it is also possible to determine the mapped Anderson model, in principle. We assume that the Anderson model is determined and solved. Since a complete gap opens in Lieb and Wu’s insulator and its residual entropy per unit cell is zero or infinitesimal in the thermodynamic limit, the scenario that \( \lambda_{c} = 0 \) and \( |\lambda_{T}| \gg 0 \) in Eq. (5.1) is only possible for the insulator: \( \Sigma_{\sigma}(e+i0) \) is analytic at \( e = 0 \), but \( \Gamma(e+i0) \) has a pole at \( e = 0 \), or just on \( \mu \). If the insulator is rigid against the movement of \( \mu \), as discussed in Sect. 2.2.2, the pole of \( \overline{\Gamma}(e+i0) \) moves as \( \mu \) moves. If \( \mu \neq \mu_{0} \), \( \overline{\Gamma}(e+i0) \) has a pole at \( e \neq 0 \) on the real axis. Since \( \Delta(e) = -\text{Im} \overline{\Gamma}(e+i0) \), as shown in Eq. (3.7), \( \Delta(e) = 0 \) for \( e \geq 0 \). If so, there is no Fermi surface in the Anderson model, so that the ground state of the Anderson model is not the normal Fermi liquid and \( \Sigma_{\sigma}(e+i0) \) is not analytic at \( e = 0 \). There is inconsistency between the possibility and rigidity of Lieb and Wu’s insulator.

Three explanations are possible for this inconsistency: One is the pinning of the chemical potential, as in Wilson’s insulator. If not only the long-range Coulomb interaction but also the formation of an electric double layer between Wilson’s insulator and its reservoir is considered, the gap center is pinned to the chemical potential of the reservoir. If a similar or different type of pinning is possible between Lieb and Wu’s insulator and its reservoir, it is possible that the band center \( e_{d} \) is adjusted in such a way that the gap center \( \rho_{0} = e_{d} + (1/2)U \) is pinned to the chemical potential of the reservoir. However, it seems plausible that there is no appropriate pinning mechanism in one dimension. Another is that Lieb and Wu’s insulator is so singular that it cannot be treated by KLT. Either the gap function or the ground-state energy is singular at \( U = 0 \) as a function of \( U \).\textsuperscript{5,11} This means that Lieb and Wu’s insulator cannot be treated by a simple perturbation in terms of \( U \). If the gap-opening or Eq. (5.1) is assumed from the beginning,\textsuperscript{27} KLT may treat Lieb and Wu’s insulator for \( \mu = \mu_{0} \); however, KLT can never treat Lieb and Wu’s insulator for \( \mu \neq \mu_{0} \). In other words, the Bethe-ansatz solution for Lieb and Wu’s insulator may be a self-consistent solution of KLT for \( \mu = \mu_{0} \) but can never for \( \mu \neq \mu_{0} \). This finding means or implies that Lieb and Wu’s insulator is unstable or impossible in the grand canonical ensemble, at least for \( \mu \neq \mu_{0} \). Then, the most probable explanation is that the ground state for \( |\mu - \mu_{0}| < (1/2)e_{0}(U) \) is not Lieb and Wu’s insulator itself, which is an eigenstate of \( \mathcal{N} \), but an electron state that is no eigenstate of \( \mathcal{N} \), a type of insulator different from Lieb and Wu’s insulator or simply the RVB-TL electron liquid in the limit \( T \rightarrow 0 \ K \). Not only an excited state but also the ground state has to be nonrigid against the movement of \( \mu \) in the grand canonical ensemble, except for Wilson’s band insulator; the ground state can be nonrigid at least if it is more or less a linear combination or mixture of different \( N \) states, e.g., because of an electron reservoir.

We assume the explicit presence of an electron reservoir in \( D \geq 1 \) dimensions. A many-body eigenstate is no eigenstate of \( \mathcal{N} \). We define the efficiency of the reservoir by\textsuperscript{27}

\[
\delta N = \sqrt{(\langle \mathcal{N} \rangle - \langle \mathcal{N} \rangle)^{2}}.
\]

(5.3)

It is plausible that \( \delta N \gg 1 \) and \( \delta N/L \rightarrow 0 \) as \( L \rightarrow +\infty \), if the reservoir is appropriate. If more or less \( \delta N > 0 \), \( \langle \mathcal{N} \rangle \) can be not only an integer but also an irrational number; \( \langle \mathcal{N} \rangle \) is continuous as a function of \( \mu \). If no symmetry breaking occurs, it is likely that the nature of electron correlation is continuous as a function of the continuous variable \( \langle \mathcal{N} \rangle \); then, it is unlikely that there exists a critical deviation \( \delta_{N} \) from the half filling such that the ground state is an insulator for \( |\langle \mathcal{N} \rangle - L| < \delta_{N} \) but is a metal for \( |\langle \mathcal{N} \rangle - L| > \delta_{N} \). This argument implies that neither Lieb and Wu’s insulator nor the Mott insulator in which a complete gap opens is possible.

In our previous paper,\textsuperscript{21} the reservoir effect is considered with a simple model in \( D \geq 1 \) dimensions in which the translational symmetry is restored by the ensemble average. If symmetry breaking is ignored, the Green function is given by

\[
G_{\sigma}(\varepsilon_{\ell}, k) = \frac{1}{\varepsilon_{\ell} + \mu - E(k) - \Sigma_{\sigma}(\varepsilon_{\ell}, k) - \Gamma_{R}(\varepsilon_{\ell})},
\]

(5.4)
where $\Gamma_R(\varepsilon \varepsilon)$ is due to hybridization with the reservoir. From the mapping condition, it follows that\(^{21}\)
\[
\Delta(\varepsilon) \geq -\text{Im} \Gamma_R(\varepsilon + i0). \tag{5.5}
\]
If the reservoir is appropriate, $-\text{Im} \Gamma_R(\varepsilon + i0) = +\varepsilon^+$. Since $\Delta(\varepsilon)$ is nonzero, $k_B T_K$ has to be more or less nonzero and the single-site $\Sigma_i(\varepsilon + i0)$ has to be more or less normal. If $\Delta(\varepsilon) < +\varepsilon^+$ is assumed, it is easy to extend the analysis in Sect. 4 to this model, regardless of $T$. If $|n(\mu) - 1| \lesssim |\varepsilon|/(DU)$, e.g., the ground state is the RVB liquid with $k_B T_K = O(|J|/D)$, $\rho_o(0) = O(1/U)$, and $\Delta(\varepsilon) = O(\varepsilon)$; the eventual $\Delta(\varepsilon)$ is consistent with the assumption of $\Delta(\varepsilon) < +\varepsilon^+$. The liquid is not rigid against the movement of $\mu$; e.g., the three-peak structure with the midband between the Hubbard bands varies with $\mu$. Since $\Delta(\varepsilon) > 0$ for $T = 0\ K$ is no assumption, it is definite that the Mott insulator at $T = 0\ K$ in which a complete gap opens is impossible. It is reasonable that the Mott insulator at $T = 0\ K$ is unstable even against the infinitesimal $\Gamma_R(\varepsilon + i0)$, because it is infinitely degenerate. Since $\Delta(\varepsilon) < +\varepsilon^+$ or $\Gamma_R(\varepsilon + i0)$ with no pole at $\varepsilon = 0$ for $T = 0\ K$ is assumed, the possibility cannot be denied that an MI transition occurs at $T = 0\ K$ and the ground state is an insulator in which the third law of thermodynamics holds. The insulator, if possible, has to be a mixture of different $N$ states and cannot be Lieb and Wu’s insulator itself, which is an eigenstate of $N'\varepsilon$; it is desirable to determine the critical $\delta N'\varepsilon$ defined above and the critical $\mu$ corresponding to $N'/L$ in order to confirm that either the transition or insulator at $T = 0\ K$ is actually possible, although either is of no physical significance.\(^{34}\)

If the reservoir is appropriate, the modification of many-body eigenstates of the Bethe-ansatz solution by the reservoir has to be small. It is, therefore, expected that
\[
\left[ \chi_{\varepsilon}(0, 0) \right]_{|\mu - \mu_0| \lesssim (1/2)c_G(U)} = O\left[ (\delta N/L)/c_G(U) \right], \tag{5.6a}
\]
\[
\left[ \chi_{\varepsilon}(0, 0) \right]_{|\mu - \mu_0| \lesssim (1/2)c_G(U)} = O\left[ (\delta N/L)/c_G(U) \right], \tag{5.6b}
\]
regardless of the ground state. If $\delta N > 0$ once, metallic configurations with $N \neq L$ contribute to any statistical average in the grand canonical ensemble. It is expected that more or less $\rho_o(0) > 0$ regardless of $T$. If so, it is easy to extend the analysis for $T > 0\ K$ in Sect. 4 to $T > 0\ K$. The ground state is the RVB-TL liquid even for $|\mu - \mu_0| \lesssim (1/2)c_G(U)$; it has to be simply that in the limit $T \to 0\ K$. If Eq. (5.6) is satisfied, many physical properties of the liquid cannot depend on $\mu$: e.g., $n(\mu) = 1$, $\chi_{\varepsilon}(0, 0) = 0$,\(^{38}\) $k_B T_K = O(|J|/D)$, $\rho_o(0) = O(1/U)$, and so on. Few properties can depend on $\mu$: e.g., the three peak structure with the midband between the Hubbard bands. The liquid is not rigid against the movement of $\mu$. It is expected that the physical properties of the liquid will be the same as those of Lieb and Wu’s insulator, expect for those closely related to the itineracy of electrons. On the other hand, the possibility cannot be denied that $\rho_o(0) = 0$ even for $\delta N > 0$. In this case, the ground state is a type of insulator different from Lieb and Wu’s insulator, because it cannot be rigid against the movement of $\mu$. It is desirable to determine which is the ground state for $|\mu - \mu_0| < (1/2)c_G(U)$ in the grand canonical ensemble, Lieb and Wu’s insulator, a type of insulator different from it, or the RVB-TL liquid,\(^{34}\) particularly in the explicit presence of a realistic and appropriate electron reservoir, in which there is no translational symmetry, $\delta N > 1$, and $\delta N/L \to 0$ as $L \to +\infty$.

5.3 RVB liquid in low dimensions

If $|J|/|k_B D| > 1$ in sufficiently low-$D$ dimensions, $T_c \ll |J|/(k_B D)$ can be satisfied. The low-$T$ phase of $T_c < |J|/(k_B D)$ is mainly studied in the present paper. Since $\rho_o(0)$ of this phase is necessarily more or less nonzero, there is no doubt that KLT can treat the phase, even if KLT cannot treat Lieb and Wu’s insulator itself. If $|\mu(\mu) - 1| \lesssim |\varepsilon|/(DU)$, the RVB liquid is stabilized in the low-$T$ phase.

First, we consider one dimension, for which $T_c = 0\ K$. The RVB liquid in one dimension is also the RVB-TL liquid. The intermediate phase with $|\mu - \mu_0| \lesssim (1/2)c_G(U)$ is also simply the RVB-TL liquid. Since Eq. (5.6) has to be satisfied in the limit $T \to 0\ K$, $n(\mu) \to 1$ and $\chi_{\varepsilon}(0, 0) \to 0$ as $T \to 0\ K$ for the intermediate phase; $n(\mu) \approx 1$ and $\chi_{\varepsilon}(0, 0) \approx 0$ for the phase at $T > 0\ K$. On the other hand, if $|\mu - \mu_0| > (1/2)c_G(U)$, $\chi_{\varepsilon}(0, 0)$ is nonzero regardless of $T$. It is expected that a metal-metal (MM) transition or crossover will occur at $\mu = \mu_0 \pm (1/2)c_G(U)$ as a function of $\mu$ between the RVB-TL liquid with nonzero $\chi_{\varepsilon}(0, 0)$ and the intermediate phase with zero or small $\chi_{\varepsilon}(0, 0)$; if an MM crossover occurs, the crossover has to be very sharp at a sufficiently low $T$ and almost a transition in the limit $T \to 0\ K$. It is also expected that the conductivity of the intermediate phase will be metallic or of a bad metal due to $2k_F$ and $4k_F$ fluctuations peculiar to one dimension but never of an activation type whose activation energy is $O[c_G(U)]$. It is expected that the physical properties of the intermediate phase will be almost the same as those of Lieb and Wu’s insulator in the canonical ensemble, except for those closely related to the itineracy of electrons.

We consider the Heisenberg limit at $T = 0\ K$. If only the RVB self-energy is considered beyond $S^A$, the spectrum of a single-particle excitation of the RVB-TL liquid is given by
\[
\xi(k) = c_J J \cos(ka) - \mu^*, \tag{5.7}
\]
where $c_J \approx 1$ and $\mu^* = 0$. The spectrum of an electron-hole pair excitation is given by
\[
\omega(q) = \xi(k + q) - \xi(k) = c_J J \left[ \cos[(k + q)a] - \cos(ka) \right], \tag{5.8}
\]
where $\cos[(k + q)a] > 0$ and $\cos(ka) < 0$. Then,
\[
c_J J \sin(qa) \leq \omega(q) \leq 2c_J J \sin(2qa/2). \tag{5.9}
\]
In the Heisenberg limit, low-energy charge fluctuations are almost completely depressed; thus, the pair excitation $\omega(q)$ is almost a spin excitation. The spin-excitation spectrum $\omega(q)$ in the Hubbard model is similar to the spin-excitation spectrum in the Heisenberg model.\(^{39}\) The similarity of the spin-excitation spectrum is evidence of the adiabatic continuation between the RVB-TL electron and spin liquids.

According to previous papers,\(^{60-62}\) the spin liquid in the Heisenberg model is the TL spin liquid; i.e., it is the RVB-TL spin liquid. This is also evidence of the adiabatic continuation between the RVB-TL electron and spin liquids.

The ground-state energy of Lieb and Wu’s insulator as a function of a complex $z = t/U$ has no singularity at $z = 0$.\(^{11}\) This fact means or implies that Lieb and Wu’s insulator adiabatically continues to the RVB-TL spin liquid; if so, the insulator also adiabatically continues to the RVB-TL electron liquid. It is certain that the RVB mechanism is also crucial for the stabilization of Lieb and Wu’s insulator. The RVB-TL
electron liquid in the intermediate phase in the grand canonical ensemble and Lieb and Wu’s insulator in the canonical ensemble are never contradictory to each other. The similarity and difference between them have to be similar to those between the RVB-TL electron and spin liquids.

Next, we consider two dimensions. The Hubbard model on the square lattice is of particular interest; no symmetry can be broken at $T > 0 \mathrm{K}$. If $U = 0$ diverges logarithmically as $\varepsilon \rightarrow 0$ because of the saddle-point van Hove singularity peculiar to two dimensions, and the Fermi surface for $U = 0$ shows a perfect nesting for $Q = Q_0$, where $Q = (\pm 1, \pm 1)(\pi/a)$, in the half-filled case. We assume that $U/|t| \gg 1$ and $\mu = \mu_0$.

The static susceptibility of the Anderson model is approximately given by Eq. (3.44): $\chi_s(0; T) \simeq 4\phi_1\rho_\mu(0)$. If $T$ is nonzero, the logarithmic divergence of $\phi_1(\rho_\mu(\varepsilon))$ as $\varepsilon \rightarrow 0$ is suppressed by the imaginary part of the self-energy. Since the suppression disappears in the limit $T \rightarrow 0 \mathrm{K}$, it is expected that $\chi_s(0; T) \rightarrow +\infty$ as $T \rightarrow 0 \mathrm{K}$. The Fermi surface shows a sharp nesting for $Q$, at least for $0 < K < |J/(2k_B)|$. The superexchange interaction $J_s(0, q)$ is maximum at $q = Q$. Thus, the half-filled ground state is presumably the Neel state with the ordering vector $Q$. The low-$T$ phase of $0 < K < |J/(2k_B)|$ is the RVB electron liquid in the critical region. We consider the $T$ dependence of the static homogeneous susceptibility; it can be described as

$$1/\chi_s(0, 0; T) = 1/\chi_s(0, Q; T) + (1/4)[\Delta_s + \Delta Q(T) - \Delta T(T)], \quad (5.10)$$

$$\Delta_s = J_s(0, Q) - J_s(0, 0) = 4|J|, \quad (5.11)$$

$$\Delta Q(T) = J_Q(0, Q; T) - J_Q(0, 0; T), \quad (5.12)$$

$$\Delta T(T) = \Lambda_T(0, Q; T) - \Lambda_T(0, 0; T), \quad (5.13)$$

from Eq. (3.37). The $T$ dependence of $\Delta_s$ can be ignored. It is expected that an anomaly will appear in $\chi_s(0, 0; T)$ of the RVB liquid in the critical region, as discussed below.

As preliminary, we consider $D$ dimensions. According to previous papers, if $\mu$ lies in the vicinity of one of the band edges and $\rho_\mu(\varepsilon)$ has a sharp peak in the vicinity of $\mu$, $J_Q(0, 0; T)$ is ferromagnetic; i.e., $J_Q(0, 0; T)$ is positively large and $J_Q(0, 0; T)$ increases almost linearly against $T$ as $T \rightarrow 0 \mathrm{K}$. On the other hand, if $\mu$ lies around the band center and the Fermi surface shows a sharp nesting, it is antiferromagnetic; i.e., $J_Q(0, Q; T)$ is positively large and $J_Q(0, Q; T)$ increases almost linearly against $T$ as $T \rightarrow 0 \mathrm{K}$. The $T$ dependence of $J_Q(0, 0; T)$ is a mechanism of the Curie-Weiss (CW) law, as will be discussed later in Sect. 5.4.

We consider two dimensions. We find that for $Q = (\pm 1, \pm 1)(\pi/a)$, so that $J_Q(0, Q; T)$ is positively large at $T \ll |J|(2k_B)$ and $J_Q(0, Q; T)$ increases as $T \rightarrow 0 \mathrm{K}$. The density of states $\rho_\mu(\varepsilon)$ has a logarithmic peak at the band center, so that $J_Q(0, 0; T)$ is also positive at $T \ll |J|(2k_B)$ and $J_Q(0, 0; T)$ increases as $T \rightarrow 0 \mathrm{K}$. Since both $\mu$ and the peak of $\rho_\mu(\varepsilon)$ are at the band center, the nesting effect is larger than the logarithmic-peak effect. Then, $\Delta Q(T) > 0$ and the $T$ dependence of $J_Q(0, Q; T)$ is much stronger than that of $J_Q(0, 0; T)$. The $T$ dependence of $\Delta Q(T)$ is large; $\Delta Q(T)$ increases as $T \rightarrow 0 \mathrm{K}$. The Néel temperature $T_N$ cannot be nonzero because of critical fluctuations, or $\Lambda(0, q; T)$; this means that the $T$ dependence of $\Lambda(0, q; T)$ is large. In general, the $q$ dependence of the mode-mode coupling term $\Lambda(0, q; T)$ is small. $\Delta T(T)$ has to be small and the $T$ dependence of the small $\Delta_T(T)$ is also small. In the critical region, the CW law is suppressed by $\Lambda(0, q; T)$ and $\chi_s(0, Q; T)$ is almost constant as a function of $T$. Thus, according to Eq. (5.10), the $T$ dependence of $1/\chi_s(0, 0; T)$ resembles that of $\Delta Q(T)$.

It is easy to extend the study in the present paper to a different type of Hubbard model, i.e., one on a different symmetry or type of lattice and/or with not only $t$ between nearest neighbors but also $t'$, $t''$, and so on between other neighbors. The superexchange interaction appears between not only nearest neighbors but also other neighbors: $J \propto |t|^2/U$, $J' \propto |t'|^2/U$, $J'' \propto |t''|^2/U$, and so on. Since the RVB mechanism is of the first order in the superexchange interaction, the eventual stabilization energy or $k_B T_k$ is the sum of the contributions of $J, J', J''$, and so on. Since $k_B T_k$ is nonzero for a finite $D$, the same qualitative conclusion as that for the Hubbard model of Eq. (2.1) can be drawn for a different type of Hubbard model.

The most interesting extension is that to the triangular lattice. If $T > 0 \mathrm{K}$, no symmetry is broken. The electron state at $0 < K < |J|(2k_B)$ in the Hubbard model is a frustrated electron liquid, and the spin state at $0 < K < |J|(2k_B)$ in the Heisenberg model is the RVB spin liquid proposed by Fazekas and Anderson. We propose that the frustrated electron liquid in the Hubbard model is simply the RVB electron liquid, and that the RVB electron and spin liquids in the Hubbard and Heisenberg models on the triangular lattice adiabatically continue to each other.

In three dimensions and higher, it is possible that $T_N \ll |J|(2k_B)$, at least, if frustration or quasi-low dimensionality is sufficient in the Hubbard and Heisenberg models. If $T_N \ll |J|(2k_B)$, it is interesting to study how magnetic properties at $T_N < T \ll |J|(2k_B)$ resemble each other between an electron liquid in the Hubbard model in the strong-coupling region, which is the RVB electron liquid, and a spin liquid in the Heisenberg model, which is the RVB spin liquid.

5.4 Itinerant electrons versus local moments

Electrons behave as local moments at $T \gg T_K$, or local moments form at $T \approx T_K$. We consider the half-filled case in infinite dimensions or in the limit $1/D \rightarrow 0$ as the most typical case. Assuming that $T > T_N$, where $T_N$ is the Néel temperature to be determined, we consider $\chi_s(0, q)$ given by Eq. (3.37) with $I_s(0, q)$ given by Eq. (3.52). As $1/D \rightarrow 0$, $k_B T_K = (|J|/D) \rightarrow 0$ and $J_s(0, q) \rightarrow 0$, because they are of higher order in $1/D$. Since $T/T_K \rightarrow +\infty$, $J_Q(0, q) \rightarrow 0$ and $\chi_s(0, q) = 1/(k_B T)$. Then,

$$\chi_s(0, q) = 1/[k_B T (1 - 4) J_s(0, q)], \quad (5.14)$$

$$T_N = J_s(0, Q)/(4k_B) = |J|/(2k_B), \quad (5.15)$$
where $Q = (±1, ±1, \cdots, ±1)/(π/a)$. The static susceptibility $χ_s(0, q)$ obeys the CW law of local-moment magnetism due to the $T$ dependence of the single-site $χ_s(0)$. Both $χ_s(0, q)$ and $T_N$ are in agreement with those in the mean-field approximation for the Heisenberg model. These agreements are reasonable because either the $1/D$ expansion theory or the mean-field approximation is rigorous in the limit $1/D → 0$.

If $T > T_N$ and $T > T_K$, $χ_s(0, q)$ is approximately given by Eq. (5.14) even for a finite $D$. If $T > T_K$, local moments form in either low or high dimensions. The Kondo energy $k_B T_K$ is also the energy scale of quantum spin fluctuations. If $T < T_K$, the ensemble of electrons or spins behaves as a liquid, i.e., an electron or spin liquid. If $T > T_K$, electrons or spins behave as local moment. Itinerant-electron magnetism and local-moment magnetism are characterized by $T_N < T_K$ and $T_N > T_K$, respectively. In sufficiently low dimensions, $T_N < T_K$ and itinerant-electron magnetism appears in either an electron model such as the Hubbard model or a spin model such as the Heisenberg model. Magnetism in the RVB electron or spin liquid is a typical type of itinerant-electron magnetism. In sufficiently high dimensions, $T_N > T_K$ and local-moment magnetism appears in either an electron or spin model. Magnetism in infinite dimensions is a typical type of local-moment magnetism.

According to Eqs. (3.37) and (3.52), the possible mechanisms of the CW law are only the $T$ dependences of $χ_s(0, q)$, $J_Q(0, q)$, and $Λ(0, q)$. According to the self-consistent renormalization theory (SCR) of spin fluctuations, the mode-mode coupling term becomes smaller as $T$ decreases in certain cases. If $Λ(0, q)$ decreases linearly against $T$ as $T$ decreases, the $T$ dependence of $Λ(0, q)$ gives the CW law; the $q$ dependence of $Λ(0, q)$ has to be small. If critical fluctuations develop as $T$ decreases, $Λ(0, q)$ increases as $T$ decreases and the $T$ dependence of $Λ(0, q)$ suppresses the CW law, as in the Hubbard model on the square lattice. It is interesting to examine which occurs because of $Λ(0, q)$ in each actual system, the CW law or the suppression of the CW law.

If $T_N < T_K$ and $T_N < T < T_K$, $J_Q(0, q)$ increases almost linearly as $T$ decreases in the two cases of $q = 0$ and $q = Q_N$ discussed above. The $T$ dependence of $J_Q(0, q)$ gives the CW law of itinerant-electron magnetism, which holds only for particular $q$’s in the vicinity of the ordering wave number. If $T_N > T_K$ and $T > T_N$, the $T$ dependence of $χ_s(0)$ gives the CW law of local-moment magnetism, in which the Curie constant does not depend on $q$ but the Weiss temperature depends on $q$, as shown in Eq. (5.14).

Either the mechanism due to the $T$ dependence of $J_Q(0, q)$ for particular $q$’s or that of the single-site $χ_s(0)$ for any $q$ is of the zeroth order in $1/D$. The mechanism due to the $T$ dependence of $Λ(0, q)$ is of higher order in $1/D$.

### 5.5 Metal-insulator transitions in actual compounds

In a multiband model, not only antiferromagnetic order but also orbital order is possible. We assume that $T_C > T_K$, where $T_C$ is the critical temperature of antiferromagnetic or orbital order. If $T > T_C$, then $T > T_K$, the entropy is $0(k_B \ln 2)$ per unit cell, and the static susceptibility obeys the CW law of local-moment magnetism. The paramagnetic phase at $T > T_C$ is simply the Mott insulator. The ordered phase at $T ≤ T_C$ is the Néel state of local moment magnetism or the type of insulator proposed by Slater.

It is possible that $T_K$ substantially depends on the symmetry or type of lattice and the lattice constant. An MI transition is possible in conjunction with such a lattice effect on $T_K$ as a function of an appropriate parameter, such as $T$, $n(\mu)$ or doping, pressure, substitution, and so on, between a high-$T_K$ metallic phase with $T_K \gg T$ on a type of lattice and a low-$T_K$ insulating phase with $T_K \lesssim T$ on a different type of lattice or the same type of lattice but with a different lattice constant. If the antiferromagnetic or orbital order appears in the low-$T_K$ insulating phase, it is the Néel state of local moment magnetism or the type of insulator proposed by Slater. If not, it is the Mott insulator. It is expected that this type of MI transition can explain MI transitions observed in many compounds. Similarly, an MM or insulator-insulator (II) transition is also possible as a function of an appropriate parameter due to the dependence of $T_K$ on the parameter in conjunction with the lattice effect.

### 5.6 Normal state for studying low-$T$ ordered phases

The RVB electron liquid studied in the present research is simply the normal state at $T > T_c$ for studying possible low-$T$ ordered phases at $T < T_c$, such as the Néel state of itinerant-electron magnetism, which is of the zeroth order in $1/D$, and an anisotropic superconducting state, which is of higher order in $1/D$, and so on. The normal state proposed by Anderson for high-temperature superconductivity in cuprate oxides has to be the RVB electron liquid studied in the present paper, rather than an exotic Fermi liquid. The study in the present research confirms the relevance of the normal state assumed in a previous theory of high-temperature superconductivity in cuprate oxides and in previous theories of itinerant-electron ferromagnetism and antiferromagnetism. The Kondo energy or the effective Fermi energy in the previous theories has to be understood as that enhanced by the RVB mechanism, if the mechanism is crucial.

### 6. Conclusions

The Hubbard model is studied. Every irreducible physical property of the Hubbard model is decomposed into single-site and multisite properties. The single-site property can be mapped to a local property of the Anderson model that is self-consistently determined to satisfy the mapping condition. Every single-site property is equal to its corresponding property of the Anderson model. Certain local properties that are not single-site properties are also equal to their corresponding properties of the Anderson model; e.g., the density of state per unit cell of the Hubbard model, which is denoted by $ρ_\mu(ε)$, is equal to that of the Anderson model.

In the field theory, the superexchange interaction arises from the virtual exchange of a pair excitation of an electron in the upper Hubbard band and a hole in the lower Hubbard band. If the on-site repulsion is $U$ and the transfer integral between nearest neighbors is $−t/\sqrt{D}$, where $D$ is the dimensionality, the exchange interaction constant between nearest neighbors is $J/D$, where $J = −4t^2/U$. This $J$ is in agreement with that given by the conventional derivation. The superexchange interaction is a multisite effect and is a higher-order effect in $1/D$.

The Kondo-lattice theory (KLT) is a perturbative theory based on the mapping to the Anderson model to include multisite terms in terms of intersite mutual interactions. Its un-
perturbed state is constructed through the mapping to the Anderson model; in principle, all the single-site terms are rigorously considered in it. The Kondo temperature or energy, $T_K$ or $k_B T_K$, is defined through the Anderson model. If $T_K > 0 \, \text{K}$ and $T$ is so low that $T \ll T_K$, the unperturbed state is the normal Fermi liquid. Since every single-site term is of the zeroth order in $1/D$ and multisite terms are of higher order in $1/D$ except for certain terms of the conventional Weiss mean field, KLT is also the $1/D$ expansion theory.

Since a gap never opens at a nonzero temperature $T$ such that $T > T_c$, where $T_c$ is $0 \, \text{K}$ for $D = 1$ and is the highest critical temperature among possible ones for $D > 2$, the density of states $\rho_T(\varepsilon)$ is more or less nonzero at $T > T_c$. If more or less $\rho_T(\varepsilon) > 0$ or $\rho_T(\varepsilon) > 0$ is seriously considered, $k_B T_K$ is also more or less nonzero. Nonzero $k_B T_K$ and $\rho_T(\varepsilon)$ have to be self-consistently determined with multisite effects to satisfy the mapping condition.

Exactly and almost half-filled cases in the strong-coupling region of $U/|t| \gg 1$ in the grand canonical ensemble are studied on the basis of KLT. The number of electrons per unit cell is denoted by $n$. If $|n - 1| \lesssim |t|/(D U)$, the resonating-valence-bond (RVB) mechanism is crucial. The Fock-type self-energy due to the superexchange interaction is the RVB self-energy. The Kondo energy is substantially enhanced by the RVB self-energy, so that $k_B T_K = O(|J|/D)$. If the dimensionality $D$ is so small that $k_B T_K \ll |J|/D$, the low-$T$ phase of $T_c < T \ll T_K$ is the RVB electron liquid, which is stabilized by the Kondo effect in conjunction with the RVB mechanism; the RVB electron liquid in one dimension is also the Tomonaga-Luttinger (TL) liquid or the RVB-TL liquid. The density of states $\rho_T(\varepsilon)$ of the RVB electron liquid has a three-peak structure with a narrow midband between the upper and lower Hubbard bands; this corresponds to the three-peak structure with the Kondo peak between two subpeaks in the Anderson model. The midband is the chemical potential within the Hubbard pseudogap. The bandwidth of the midband is $O(k_B T_K)$, $O(|J|/D)$, or $O(2^D/(D U))$; its spectral weight is $O(2^D/(D U)^2)$ per unit cell; and $\rho_T(0) = O(1/U)$. Since the midband does not appear in the Heisenberg limit, the RVB electron liquid in the Heisenberg limit is a quasi-spin liquid. The quasi-spin liquid shows metallic conductivity.

According to previous studies of the Kondo effect, the local electron liquid in the Anderson model and the local spin liquid in the s-d model adiabatically continue to each other, although the local gauge symmetry does not exist in the Anderson model but exists in the s-d model. According to the scaling theory for the Anderson localization, if no symmetry breaking occurs at a metal-insulator transition, the metallic and insulating phases adiabatically continue to each other. On the basis of these previous studies and the study in the present paper, it is proposed that the RVB electron liquid in the Hubbard model and the RVB spin liquid in the Heisenberg model adiabatically continue to each other, although the local gauge symmetry does not exist in the Hubbard model and the condensate of the RVB electron liquid is metallic, while the local gauge symmetry exists in the Heisenberg model and the conductivity of the RVB spin liquid is zero.

If $T \gtrsim T_K$, thermal spin fluctuations are more dominant than quantum spin fluctuations, local moments forms, and the entropy is as large as $k_B \ln 2$ per unit cell. The high-$T$ phase where $T \gtrsim T_K$ is the Mott insulator. The Mott insulator, which is a high-$T$ phase with a large entropy, never contradicts the RVB liquid, which is a low-$T$ phase with a small entropy.

According to the Bethe-ansatz solution, the half-filled ground state in the canonical ensemble in one dimension is the Lieb and Wu’s insulator. The insulating ground state never contradicts the RVB-TL liquid at $0 \, \text{K} < T \ll |J|/k_B$ in the grand canonical ensemble. It is desirable to determine which is the half-filled ground state in the grand canonical ensemble in one dimension, Lieb and Wu’s insulator, a type of insulator different from it, or the RVB-TL liquid.

**Appendix A: Sum Rule for $\Delta(\varepsilon)$**

We consider

$$F(\varepsilon + i 0) = [\varepsilon + \mu - \varepsilon_d - \Sigma(\varepsilon + i 0)] - 1/R_\sigma(\varepsilon + i 0).$$

(A-1)

According to the mapping condition of Eq. (3.12),

$$\text{Im} F(\varepsilon + i 0) = -\Delta(\varepsilon).$$

(A-2)

Since $\Delta(\varepsilon) \equiv (\varepsilon + i 0, k) \rightarrow 0$ as $\varepsilon \rightarrow \pm \infty$, $\lim_{\varepsilon \rightarrow \pm \infty} F(\varepsilon + i 0) = (2t^2/\varepsilon) + O(1/\varepsilon^2)$. (A-3)

Since $F(\varepsilon + i 0)$ is analytic in the upper-half complex plane, according to Eqs. (A-2) and (A-3),

$$\int_{-\infty}^{+\infty} d\varepsilon \Delta(\varepsilon) = 2\pi t^2.$$  

(A-4)

**Appendix B: Theoretical Constraint for $1/\tilde{\phi}_1$**

**B.1 Lower limit of $1/\tilde{\phi}_1$**

We assume that $U/|t| \gg 1$, $\mu = \mu_0$, and $T_c < T \ll T_K$. The density of states $\rho_T(\varepsilon)$ has a symmetric three-peak structure with the midband between the Hubbard bands.

We consider the contribution from the midband to the integration in Eq. (B-4). According to Eq. (3.42), $|1\text{Im}\Sigma(\varepsilon+i0)| = O(\phi_1 k_B T^2/T_K)$; it can be ignored for $T \ll T_K$. According to Eq. (4.24), $\text{Re} R_\sigma(\varepsilon+i0) = 0$, $\Delta(0) = 1/[\pi\rho_T(0)]$. According to Eqs. (3.45) and (4.23c), $1/\rho_T(0) = O(\phi_1 k_B T_K)$ and $k_B T_K = O(t^2/(D U))$, respectively. Then,

$$\Delta(0) = O\bigl[[\tilde{\phi}_1 t^2]/(D U)\bigr].$$

(B-1)

Since $\tilde{\phi}_1 \gg 1$, $\Delta(0)$ is large; $\Delta(\varepsilon)$ has to have a peak at $\varepsilon = 0$ in order to satisfy Eq. (A-4). Since the peak width is $O(k_B T_K)$ or $O(t^2/(D U))$ and the peak height is given by (B-1), the contribution from the midband is as large as

$$\int_{-O(k_B T_K)}^{t+O(k_B T_K)} d\varepsilon \Delta(\varepsilon) = O(\phi_1 t^4/(D U)^2).$$

(B-2)

According to the sum rule of Eq. (A-4), Eq. (B-2) has to be smaller than $2\pi t^2$. Then,

$$1/\tilde{\phi}_1 \geq O(\pi^2/(D U)^2).$$

(B-3)

We consider the contribution from the Hubbard bands to the integration in Eq. (A-4). Since $\rho_T(\varepsilon) = -1/(\pi\Im I_{R_\sigma}^2(\varepsilon+i0))$ has peaks at $\varepsilon \approx \pm U/2$, $\text{Re} R_\sigma(\varepsilon+i0) = 0$ for $\varepsilon = \pm U/2$. The peak height and bandwidth are $\rho_T(\varepsilon) = O(1/|t|)$ and $W_{H1} = O(|t|)$, respectively. According to Eq. (4.24), since $|1\text{Im}\Sigma(\varepsilon+i0)| = O(|t|)$, $\Delta(\varepsilon) = O(|t|)$. The contribution from the Hubbard bands is as large as $\Delta(\varepsilon) W_{H1} = O(t^2)$, which is consistent with Eq. (A-4).
Asymptotic behavior of $\frac{1}{\phi_1}$

We consider $\Delta(\varepsilon)$ defined by Eq. (3.7). It is given in terms of $V_0$ and $E_c(k)$. Within KLT, it can be assumed without the loss of generality that $V_k$ is constant: $V_k = V$. Then,

$$\Delta(\varepsilon) = \pi |V|^2 \rho_c(\varepsilon),$$  \hspace{1cm} (B-4)

$$\rho_c(\varepsilon) = \frac{1}{L} \sum_k \delta[\varepsilon + \mu - E_c(k)].$$  \hspace{1cm} (B-5)

According to the sum rule of Eq. (A-4),

$$\pi |V|^2 = 2t^2.$$  \hspace{1cm} (B-6)

In the s-d or Heisenberg limit of $U/|t| \to +\infty$, with $J = -4t^2/U$ kept constant, the Anderson model can be mapped to the s-d model with the s-d exchange interaction constant of

$$\tilde{J}_{s-d} = -4|V|^2/U = -(8/\pi)(t^2/U).$$  \hspace{1cm} (B-7)

The dimensionless coupling constant is given by

$$\tilde{g}(\varepsilon) = \tilde{J}_{s-d} \rho_c(\varepsilon) = -4/(\pi U) \Delta(\varepsilon).$$  \hspace{1cm} (B-8)

If $\tilde{g}(\varepsilon)$ is constant as a function of $\varepsilon$, $T_c$ is given by

$$k_B T_K = W_c e^{-1/\tilde{g}(0)},$$  \hspace{1cm} (B-9)

in the most-divergent approximation,\(^6\) where $W_c$ is a half of the conduction bandwidth.

The energy dependence of $\tilde{g}(\varepsilon)$ has to be considered in the mapped s-d model. According to the scaling theory for the s-d model,\(^{35,77}\) high-energy processes substantially renormalize fixed-point or eventual low-energy properties, but they can cause no symmetry breaking. Thus, whether the eventual $k_B T_K$ is zero or nonzero depends on whether the bare $\tilde{g}(0)$ is zero or nonzero. If $\tilde{g}(0) > 0$, the eventual $k_B T_K$ is nonzero; if $\tilde{g}(0) = 0$, the eventual $k_B T_K$ is zero.

According to Eqs. (B-1) and (B-8), it follows that

$$|\tilde{g}(0)| = O(\tilde{\rho}_1 t^2/(DU^2)).$$  \hspace{1cm} (B-10)

If $|\tilde{g}(0)| \to 0$ as $U/|t| \to +\infty$, it is inconsistent with nonzero $k_B T_K$ in the Heisenberg limit; if $|\tilde{g}(0)| \to +\infty$ as $U/|t| \to +\infty$, it is inconsistent with Eq. (B-3). Since $k_B T_K = O(1/D)$, according to Eq. (B-9), $\tilde{g}(0)$ has to be the zeroth order in $1/D$. Since $|\tilde{g}(0)|$ has to be nonzero and finite in the limit of either $U/|t| \to +\infty$ or $1/D \to 0$,

$$1/\tilde{\rho}_1 = O[t^2/(DU^2)].$$  \hspace{1cm} (B-11)

Appendix C: Proof of an Equality

There is a useful relationship between $\Xi_D$ defined by Eq. (4.7) and $\pi_{xx}(0)$ defined by Eq. (4.33), as studied below. In the presence of magnetic impurities,

$$\Xi_D = -\frac{1}{\pi L} \sum_k \varphi_D(k) \int_{-\infty}^{+\infty} df \phi_+^*(\varepsilon) \text{Im} \bar{g}_\sigma(\varepsilon + i0, k)$$

$$= -\frac{\sqrt{D}}{\pi L} \sum_k \cos(k_1 a) \int_{-\infty}^{+\infty} df \phi_+^*(\varepsilon) \text{Im} \bar{g}_\sigma(\varepsilon + i0, k),$$  \hspace{1cm} (C-1)

$$\pi_{xx}(0) = \frac{2}{\pi L} \sum_k \sin^2(k_1 a) \int_{-\infty}^{+\infty} df \phi_+^*(\varepsilon) \text{Im} \bar{g}_\sigma(\varepsilon + i0, k)$$

$$\times [\text{Re} \bar{g}_\sigma(\varepsilon + i0, k)].$$  \hspace{1cm} (C-2)

Equation (C-1) is also given in the integration form by

$$\Xi_D = \frac{\sqrt{D} a^4}{(2\pi)^4} \int_{-\pi/a}^{+\pi/a} dk_1 \int_{-\pi/a}^{+\pi/a} \cos(k_1 a)$$

$$\times \int_{-\infty}^{+\infty} df \phi_+^*(\varepsilon) \text{Im} \bar{g}_\sigma(\varepsilon + i0, k).$$  \hspace{1cm} (C-3)

By the partial integration of Eq. (C-3) with respect to $k_1$,

$$\Xi_D = 2t^* \frac{a^4}{(2\pi)^4} \int_{-\pi/a}^{+\pi/a} dk_1 \int_{-\pi/a}^{+\pi/a} \cos(k_1 a)$$

$$\times \int_{-\infty}^{+\infty} df \phi_+^*(\varepsilon) \text{Im} \bar{g}_\sigma(\varepsilon + i0, k) [\text{Re} \bar{g}_\sigma(\varepsilon + i0, k)].$$  \hspace{1cm} (C-4)

This is also given in the sum form by

$$\Xi_D = 2t^* \frac{2}{\pi L} \sum_k \sin^2(k_1 a) \int_{-\infty}^{+\infty} df \phi_+^*(\varepsilon) \text{Im} \bar{g}_\sigma(\varepsilon + i0, k)$$

$$\times [\text{Re} \bar{g}_\sigma(\varepsilon + i0, k)].$$  \hspace{1cm} (C-5)

It immediately follows that

$$\Xi_D = 2t^* \pi_{xx}(0).$$  \hspace{1cm} (C-6)

Appendix D: On the Rigorosity of $S^3_A$

Not only all the single-site terms but also four types of the conventional Weiss mean field, which are multisite terms, are of the zeroth order in $1/D$; spin density wave or magnetism and orbital order,\(^{29}\) which are possible for $U/|t| > 0$, and charge density wave and isotropic s-wave or BCS superconductivity, which are possible for $U/|t| < 0$. All the other multisite terms are of higher order in $1/D$. Since $S^3_A$ can act on no conventional Weiss mean field or no symmetry breaking, $S^3_A$ is not necessarily rigorous even in the limit $1/D \to 0$; it is expected that $S^3_A$ will be rigorous in the limit $1/D \to 0$, if the Hilbert space is constrained within the subspace where no symmetry is allowed to be broken. The purpose of this Appendix is to examine whether $S^3_A$ is rigorous in the limit $1/D \to 0$ within the Hilbert subspace. We consider the Hubbard model of Eq. (2.1); the absolute bandwidth of it is $4\sqrt{D}/|t|$. We denote $\phi_1$ under $S^3_A$ by $\phi_{S^3_A}$, $\phi_{S^3_A}(T)$, or $\phi_{S^3_A}(D, T)$, depending on necessity or sufficiency; $\phi_1$ is used for that beyond $S^3_A$ or that of KLT.

If $n(\mu) \neq 1$, the Mott insulator at $T = 0$ K is impossible either under or beyond $S^3_A$; $1/\phi_{S^3_A} > 0$ and $1/\phi_1 > 0$. Since $1/\phi_1 \to 1/\phi_{S^3_A} > 0$ as $1/D \to 0$, $S^3_A$ is equivalent to KLT in the limit $1/D \to 0$ and rigorous in the limit $1/D \to 0$ within the Hilbert subspace. Then, the key issue is whether the Mott insulator is possible at $T = 0$ K for the half filling. In the following part, we assume the half filling in the canonical or grand canonical ensemble: $N = L$ or $n(\mu) = 1$.

There is a well-known scenario for the Mott insulator and transition, which is based on previous studies.\(^7,10\) If the absolute bandwidth is $4\sqrt{D}/|t|$, the ground state is a metal for $U \leq 4\sqrt{D}/|t|$ and is the Mott insulator at least for $U > 4\sqrt{D}/|t|$. If $T = 0$ K, e.g., the Mott transition occurs at $U = 4\sqrt{D}/|t|$ as a function of $U$. A complete gap opens in the Mott insulator at $T = 0$ K; the gap is as large as $U - 4\sqrt{D}/|t|$. The numerical study,\(^{29}\) which is under $S^3_A$, confirms this scenario; in addition, it shows that hysteresis appears in the Mott transition. On the other hand, the study in Sect. 5.1, which is beyond $S^3_A$,
shows that what is stabilized in the nonzero and low-$T$ phase of $0 < T < |J|/(k_B D)$ for $U/|t| > 1$ is not the Mott insulator but the RVB liquid. The scenario is not relevant beyond $S^3A$, at least for $0 < T < |J|/(k_B D)$. Since the RVB mechanism, which appears only beyond $S^3A$, is never considered in any stage or aspect of the scenario, it is expected that the scenario will be relevant only under $S^3A$, even if it is relevant.

In the following part, we assume that $U > 4\sqrt{D}|t|$.

If the Mott insulator is possible at $T = 0$ K in the canonical ensemble, it is possible only for $N = L$ but never for $N \neq L$. If so, and if the reservoir effect is only implicitly treated through the statistical average, the Mott insulator is also possible at $T = 0$ K in the grand canonical ensemble; the insulator is rigid against the movement of $\mu$. However, since the single-site $\sigma_\mu(\varepsilon + i0)$ has to have a pole at $\varepsilon = 0$ or just on $\mu$, as discussed in Sect. 5.1, the Mott insulator cannot be rigid against the movement of $\mu$. If the Mott insulator at $T = 0$ K is possible, there is inconsistency between its possibility and rigidity. The inconsistence means or implies that the Mott insulator at $T = 0$ K is impossible at least in the grand canonical ensemble, even if it is possible in the canonical ensemble. The critical argument given above is almost in parallel with that given in Sect. 5.2 against the possibility of Lieb and Wu’s insulator. In the following part, we assume the grand canonical ensemble.

The Mott insulator at $T = 0$ K is infinitely degenerate. In general, the ground state that is infinitely degenerate is unstable even against an infinitesimal perturbation; the third law of thermodynamics is mainly based on this fact. It is doubtful whether the Mott insulator at $T = 0$ K is stable, particularly in the explicit presence of an electron reservoir. This critical argument can be confirmed at least in the simple reservoir model, as studied in Sect. 5.2.

Either of the two critical arguments above casts doubt that the well-known scenario is not relevant for $T = 0$ K, even under $S^3A$. We do not exclude another scenario that the Mott insulator is impossible at $T = 0$ K, even under $S^3A$. If $T > 0$ K, more or less $\rho_\mu(0) > 0$; the single-site $\sigma_\mu(\varepsilon + i0)$ can have no pole on the real axis and can be expanded in the form of Eq. (3.42). Thus, more or less $1/\tilde{\delta}_S^3A(T) > 0$ for $T > 0$ K. If the ground state is the Mott insulator under $S^3A$, $1/\tilde{\delta}_S^3A(T) > 0$ as $T \to 0$ K and $1/\tilde{\delta}_S^3A(0) = 0$. If the ground state is a metal under $S^3A$, $1/\tilde{\delta}_S^3A(T) > 0$ for $T > 0$ K. On the other hand, if the RVB mechanism is considered, $1/\tilde{\phi}_1 = |t|^2/(DU^2)$, as shown in Eq. (B.11). As the asymptotic behavior of $1/\tilde{\phi}_1$ as $U/|t| \to +\infty$ and $1/D \to 0$, $1/\tilde{\delta}_S^3A$ is reasonable to assume that

$$1/\tilde{\phi}_1 = \max \{ O[^2/(DU^2)], 1/\tilde{\delta}_S^3A(T) \}. \tag{1-1}$$

We call the limit of $1/D \to 0$ and $T \to 0$ K a double limit. The issue to be studied is simply whether the double limit is unique; $S^3A$ for $T = 0$ K corresponds to the limit of $1/D \to 0$ followed by $T \to 0$ K beyond $S^3A$.

First, we assume that the Mott insulator is possible at $T = 0$ K under $S^3A$, following the well-known scenario: $1/\tilde{\delta}_S^3A(T) \to 0$ as $T \to 0$ K. If the double limit is taken in such a way that $t^2/(DU^2) \ll 1/\tilde{\delta}_S^3A(T)$ is kept satisfied, KLT is reduced to $S^3A$; the Mott insulator is stabilized. If the double limit is taken in such a way that $t^2/(DU^2) \gg 1/\tilde{\delta}_S^3A(T)$ and $t^2/(DU^2) \gg k_BT$ are kept satisfied, KLT is not reduced to $S^3A$; the RVB liquid is stabilized. The liquid is an extremely bad metal with $k_BT(t^2/(DU^2)) \to 0$, $\rho_\mu(0) = O(1/U) > 0$. Since there is a slight difference between the two types of limit, the double limit is not unique. Thus, $S^3A$ is not necessarily equivalent to KLT in the limit $1/D \to 0$ nor necessarily rigorous even in the limit $1/D \to 0$ within the Hilbert subspace.

Next, we assume that the Mott insulator is impossible at $T = 0$ K under $S^3A$, against the well-known scenario: $1/\tilde{\delta}_S^3A(D, T) > 0$ for $T \geq 0$ K. We consider, e.g., the case of $T = 0$ K. According to Eq. (D.1), a crossover $D_c$ is defined by $t^2/(DU^2) = 1/\tilde{\delta}_S^3A(D_c, 0)$; if $\tilde{\delta}_S^3A(D, 0) K$ depends on the reservoir efficiency $\delta N$ defined by Eq. (5.3), $D_c$ also depends on it, as will be discussed later. If $D < D_c$, the ground state is the RVB liquid; $k_BT(0) = O[^2/(DU^2)]$ and $\rho_\mu(0) = O(1/U)$. If $D \gg D_c$, the ground state is the normal Fermi liquid in which the RVB mechanism is not crucial; $k_BT(0) = O[^2/(DU^2)]$ and $\rho_\mu(0)$ is simply given by that for $U = 0$. As a function of $U$, $\rho_\mu(0)$ is not monotonous and is minimal at approximately $U$ such that $t^2/(DU^2) = 1/\tilde{\delta}_S^3A(D, 0)$; as a function of $D$, $\rho_\mu(0)$ is almost constant for $D \ll D_c$, an increasing function for $D$ such that $D \gg D_c$ but not $D \gg D_c$, and almost constant for $D \gg D_c$. It is easy to show that the double limit is unique. Thus, $S^3A$ is equivalent to KLT in the limit $1/D \to 0$ and rigorous in the limit $1/D \to 0$ within the Hilbert subspace.

If the reservoir effect is only implicitly treated through the statistical average, $\delta N = 0$ for $T = 0$ K, unless the ground state is degenerate between different $N$ states. If the Mott insulator is possible at $T = 0$ K for $\delta N = 0$ under $S^3A$, $1/\tilde{\delta}_S^3A(0) > 0$ for $\delta N > 0$ and $1/\tilde{\delta}_S^3A(0) = 0$ as $\delta N \to 0$ in the presence of an electron reservoir. If so, the crossover $D_c$ depends on $\delta N$ in such a way that $D_c \to +\infty$ as $\delta N \to 0$; $S^3A$ is rigorous in the limit $1/D \to 0$ within the Hilbert subspace for $\delta N > 0$ but not for $\delta N = 0$.

We conclude this Appendix. Two critical arguments are given against the possibility of the Mott insulator at $T = 0$ K, in addition to those given in Sect. 5. Whether $S^3A$ is rigorous in the limit $1/D \to 0$ within the constrained Hilbert subspace where no symmetry is allowed to be broken depends on whether the Mott insulator is possible at $T = 0$ K for the half filling under $S^3A$. If possible, $S^3A$ is not necessarily rigorous; if not, $S^3A$ is rigorous. It is desirable to determine whether the Mott insulator is possible at $T = 0$ K under $S^3A$, or the third law of thermodynamics can be broken under $S^3A$, particularly in the explicit presence of an electron reservoir.

7) N. F. Mott, Metal-Insulator Transition (Taylor & Francis, London, 1974).
12) If $N$ is odd, e.g., the ground state can never be a singlet and the residual entropy can never be zero.
A symmetry-broken state is stable against any perturbation, such as the movement of $\mu$, impurity scattering, and so on, if the perturbation is sufficiently small; i.e., it is rigid against the perturbation. However, either its order parameter or gap depends on $\mu$, i.e., it is not rigid against the movement of $\mu$. The rigidity against the movement of $\mu$ is never the conventional rigidity of a symmetry-broken state.

In Wilson’s band insulator, the volume of the Fermi surface is zero in one of the particle and hole pictures but is as large as the volume of the Brillouin zone in the other.

The gap function of a symmetry-broken state below $T_c$ is singular at $U = 0$ or $J = 0$, depending on the perturbative scheme in terms of $U$ or $J = -4t^2/|U|$, as $c_{\sigma}(U)$ of Lieb and Wu’s insulator as a function of $U$. This singularity or the symmetry-broken state can be treated by the Feynman-diagram method, if an infinitesimal symmetry-breaking field is introduced, or if the opening of a gap is assumed from the beginning.

The superexchange interaction can be ferromagnetic if the Hund coupling is large in a multiband model. It is likely that itinerant-electron ferromagnetic instability is possible only in a multiband model.
