Keywords: exosome; amyloid-beta (Aβ); Alzheimer disease; glycosphingolipid

Background: Exosome, a type of extracellular vesicles, can associate with Aβ in vitro.

Results: Intracerebrally injected exosomes trapped Aβ on surface glycosphingolipids and transported it into microglia in AD mouse brains, resulting in reductions in Aβ pathology.

Conclusion: Exogenous exosomes act as potent scavengers for Aβ in mouse brains.

Significance: The findings provide a novel therapeutic approach for AD.

ABSTRACT

Elevated levels of amyloid-β peptide (Aβ) in the human brain are linked to the pathogenesis of Alzheimer disease (AD). Recent in vitro studies have demonstrated that extracellular Aβ can bind to exosomes, which are cell-secreted nanovesicles with lipid membranes that are known to transport their cargos intercellularly. Such findings suggest that the exosomes are involved in Aβ metabolism in brain. Here, we found that neuroblastoma-derived exosomes exogenously injected into mouse brains trapped Aβ and with the associated Aβ were internalized into brain-resident phagocyte microglia. Accordingly, continuous intracerebral administration of the exosomes into amyloid-β precursor protein (APP) transgenic mice resulted in marked reductions in Aβ levels,
amyloid depositions, and Aβ-mediated synaptotoxicity in the hippocampus. In addition, we determined that glycosphingolipids (GSLs), a group of membrane glycolipids, are highly abundant in the exosomes, and the enriched glycan of the GSLs are essential for Aβ binding and assembly on the exosomes, both in vitro and in vivo. Our data demonstrate that intracerebrally administered exosomes can act as potent scavengers for Aβ by carrying it on the exosome surface GSLs, and suggest a role of exosomes in Aβ clearance in the central nervous system. Improving Aβ clearance by exosome administration would provide a novel therapeutic intervention for AD.

Alzheimer disease (AD), a common dementia, is pathologically characterized by the presence of amyloid-β peptide (Aβ)-containing senile plaques within the brain. In familial AD, genetic mutations cause increased production of Aβ (1), whereas in far more common sporadic cases, Aβ generation is normal, but its clearance is impaired (2). Elevated levels of Aβ, caused by an imbalance in its metabolism, are linked to synaptic and nerve loss, which likely manifest as progressive cognitive deficits in AD (3).

Exosomes represent a subtype of secreted membrane vesicles (40-100 nm in diameter) of endosomal origin that are released from various types of cells including neurons (4). Exosomes serve to remove and discard unwanted proteins into a drainage system; they are also known to intercellularly shuttle their cargo: a specific set of proteins, RNAs, and lipids (5). Recently, exosomes were reported to associate with a portion of extracellular amyloid-β precursor protein (APP) and its metabolites, including C-terminal fragments (CTFs), amyloid intracellular domain (AICD), and Aβ, in cultures of human wild-type or mutant human APP-expressing neuroblastoma cells (6,7). In addition, exosomal proteins such as Alix and flotilllin-1 were identified around neuritic plaques in AD brains (6). Similarly, our previous study demonstrated that exosomes released from neuroblastoma or primary cortical neurons can bind to synthetic or endogenous Aβ, and promote Aβ fibril formation on their surface in vitro (8). Furthermore, exosome-bound Aβ is incorporated into microglia for degradation, suggesting that exosomes may act as a mediator for Aβ elimination in brains (8). Here, we demonstrated that long-term intracerebral administration of exosomes to the brain of APP transgenic mice resulted in a marked reduction in Aβ levels, amyloid depositions and Aβ-mediated synaptotoxicity. We also clarified that glycosphingolipids (GSLs) abundant in the exosomes were essential for Aβ binding on the exosome surface.

EXPERIMENTAL PROCEDURES

Cell cultures - Murine neuroblastoma Neuro2a (N2a) cells were maintained in Dulbecco’s modified Eagle’s medium (Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum. The murine microglial cell line BV-2 was purchased from National Cancer Institute (Istituto Nazionale per la Ricerca sul Cancro, Genova, Italy) and was cultured in RPMI1640 (Invitrogen) supplemented with 10% fetal bovine serum and 2 mM L-glutamine.

Animals - All animal experiments were conducted under a protocol approved by the animal care committees of Hokkaido University. Wild type C57BL/6 mice were purchased from Japan SLC Inc. (Hamamatsu, Japan). Heterozygotic transgenic mice that express the human APP bearing the Swedish and Indiana (KM670/671NL, V717F) mutations (APPswInd or J20 strain) were from the Jackson Laboratory (Bar
Harbor, ME) and maintained in barrier facilities.

**Exosome isolation** - Exosomes were prepared from culture supernatants of N2a cells as described previously (9). Briefly, one day before exosome isolation, culture medium was replaced with serum-free medium. The culture supernatants were collected and sequentially centrifuged at 3,000g for 10 min, at 4,000g for 10 min, and at 10,000g for 30 min to remove cells, dead cells, and debris, then spun again at 100,000g for 1 hour to obtain exosomes as pellets.

For sucrose gradient analysis, each exosome pellet (100 µg protein) was loaded onto 10 ml of a sucrose gradient (0.25-2.3M sucrose in 20 mM HEPES, 10 ml) and centrifuged at 100,000g for 18 h. After centrifugation, 1 ml fractions were collected, diluted with 20 mM HEPES, and precipitated by centrifugation for 1 hour at 100,000g. The resulting pellets were resuspended in PBS and subjected to Western blot analysis.

**Electron microscopy** - Exosomes (100 µg protein/ml) were re-suspended in 50 mM Tris/150 mM NaCl buffer, pH 7.6 (TBS) and applied to a grid covered with collodion. For Aβ binding experiments exosomes (100 µg protein/ml) were incubated with Aβ1-42 (15 µM) in TBS at 37 ºC for 5 h after pre-treating with or without EGCase. Exosome mixtures were then applied to the grid. Exosomes were negatively stained with 2% phosphotungstic acid. Transmission images were acquired using an HD-2000 (Hitachi, Tokyo, Japan) or JEM-1400Plus (JEOL Ltd. Tokyo, Japan) transmission electron microscope.

**Dynamic light scattering** - Exosomes (untreated or treated with EGCase) were suspended in TBS at 100 µg protein/ml. The particle size of the exosomes was measured by dynamic light scattering using a DelsaNano HC (Beckmann Coulter).

**Injection and isolation of biotinylated exosomes** - Exosomes were biotinylated with EZ-link sulfo-NHS Biotin (Pierce, Rockford, IL), according to the manufacturer’s protocol with minor modifications. Briefly, the exosomes were suspended in PBS (150 µg protein/ml) and incubated with biotin reagent (1 mg/ml) at room temperature for 30 min. The biotinylated exosomes were isolated by ultracentrifugation at 100,000g for 1h at 4ºC, and re-suspended in PBS. For detecting co-precipitated Aβ, two microliter of the 5 µg/µl biotin-exosome solution was injected into the right hippocampus of APP mouse (4-month-old) using stereotaxic coordinates and keep for 3h. The biotinylated exosomes in the homogenates of the hippocampus were precipitated using streptavidin microbeads according to the protocol in a μMACS streptavidin kit (Miltenyi Biotech, Bergisch Gladbach, German). Co-precipitated Aβ was analyzed with Western blotting or ELISA following the solubilization of the exosomes in SDS sample buffer or guanidine buffer, respectively.

**SDS-PAGE and Western blotting** - SDS-PAGE and Western blot analysis were performed according to the standard methods of Laemmli. To detect target proteins, we employed as a primary antibody monoclonal antibodies against Alix (BD Bioscience, San Jose, CA), APP CTFs (Sigma), actin (Sigma), Aβ (6E10, Signet, Dedham, MA), or nepralysin (Santa Cruz Biotechnology), or rabbit polyclonal antibodies against flottilin-1, endothelin converting enzyme (ECE)-1, (Santa Cruz Biotechnology) or insulin degrading enzyme (IDE, abcam), and as a secondary antibody an anti-mouse IgG-HRP antibody(GE Healthcare), or anti-rabbit IgG-HRP antibody (GE Healthcare). To detect the ganglioside GM1, we used horse radish peroxidase (HRP)-conjugated cholera toxin B subunit (CTB) from Sigma. Bands were visualized using a combination of an ECL Plus kit (GE Healthcare) and an LAS4000 imaging system.
Fluorescence labeling for the exosomes -

Exosomes were stained with the red fluorescence dye PKH26 (Sigma) as described previously (8). Briefly, the exosomes were re-suspended in diluent C (Sigma) and incubated with PKH26 at room temperature for 5 minutes. The reaction was stopped by addition of 1% bovine serum albumin. The PKH26-labeled exosomes were precipitated again by ultracentrifugation at 100,000g at 4°C for 1 hour.

Exosome isolation from murine CSF - CSF was collected from the cisterna magna of 2-month-old C57BL/6 mice as previously described (10). Exosomes were isolated from the CSF using a method similar to that described above for isolation from culture medium.

Analysis of exosomal particle number - A qNano System (Izon Science, Ltd) was employed to analyze the particle densities of N2a- and mouse CSF-derived exosomes resuspended in PBS.

Exosome administration in mouse brains - Mice were continuously treated with exosome solution (2 mg protein/ml) or vehicle (PBS) by Alzet minipump (model 1002) at 0.25 µl/h for 14 days. Mice were placed in a stereotactic instrument (NARISHIGE, Tokyo, Japan) and stainless steel cannulas of Alzet Brain Infusion Kit3 were implanted into the right lateral ventricle (mediolateral, -0.8 mm; dorsoventral -3.0 mm) or hippocampus (anteroposterior, -2.0 mm; mediolateral, -1.3 mm; dorsoventral -2.2 mm). After 14-day infusion, mice were then transcardially perfused with cold heparin/PBS. The right hemibrain was fixed with 4% paraformaldehyde/PBS at 4°C for 48h for use in immunohistochemistry, and the left hemibrain was rapidly frozen with liquid nitrogen and stored at -80°C for later analysis.

For single injection studies, PKH-labeled exosomes or a conjugate of PKH-exosomes with fluorescent Aβ (4 µg exosome protein in 2µl PBS) were injected into the right hippocampus or the lateral ventricle of non-transgenic mice using stereotaxic coordinates as described above. To obtain the conjugates of the exosomes with Aβ, PKH-exosomes (100 µg/ml) were incubated with Aβ₁₄₀ in TBS at 37°C for 24h, then centrifuged at 100,000g for 1h to remove free Aβ. At 3 or 24h post injection, the mouse brains were prepared as described above for immunohistochemistry.

Immunohistochemistry - The tissue sections were cut with a cryostat (Leica CM3050S) and post-fixed with 4% paraformaldehyde/PBS. After a blocking with 5% BSA, 16 µm-thick sections were immunostained with monoclonal antibodies against, Iba1 (Wako), βIII tublin (Promega), or glial fibrillary acidic protein (GFAP, SHIMA laboratory), followed by visualization with AlexaFluor488-conjugated anti-IgG. Serial 30 µm-thickness of brain sections were immunostained with monoclonal antibody against Aβ (4G8, Covance) after a brief formic acid treatment and the signals were visualized using ABC elite kit (Vector Laboratories). Confocal images were obtained using an Olympus Fluoview FV10i microscope. The Aβ plaques were estimated as the percentage of the immunopositive area (positive pixel) to the examined area (total pixel) using ImageJ software.

Aβ ELISA - Aβ levels were determined using a sandwich enzyme-linked immunosorbent assay (ELISA). The kits for Aβ₁₄₀ and Aβ₁₄₂ were obtained from Wako (Osaka, Japan), and that for Aβ₁₃₈ was from IBL (Gunma, Japan). Mouse hippocampus or exosomes were homogenized in 4M guanidine-HCl buffer (pH 8.0) with an ultrasonic homogenizer (TAITEC, Saitama, Japan). After incubation at room temperature for 3 h, the homogenates were further diluted with 0.1% BSA/PBS and centrifuged at 16,000g for 20min.
The resulting supernatants were then applied to the ELISA. All samples were measured in duplicate.

**Evaluation of synaptic densities** - Synaptophysin-immunoreactive synaptic densities were quantified according to the methods of Mucke et al (11) with minor modifications. The right hemisphere of each APP mouse brain was sagittally cut into 16 µm-thick sections using a freezing microtome. The serial sections were incubated with a monoclonal antibody against synaptophysin (D35E4, Cell Signaling), followed by incubation with AlexaFluor488-bound anti-IgG. Immunofluorescent signals were visualized using an Olympus Fluoview FV10i microscope. The linear range of the synaptophysin-positive fluorescence intensities in nontransgenic control sections was determined, and the same setting was used to analyze all of the following images. For each mouse, 9 confocal images were captured in three sections per right hemisphere of the brain, and each image covered an area 5500 µm² in the molecular layer of the dentate gyrus. The synaptophysin-immunoreactive synaptic densities were estimated as a percentage of the immunostained area (positive pixel) to the selected image area (total pixel) using ImageJ software.

**Thioflavin-S (ThS) staining** - Brain sections (30 µm thick) were oxidized with 0.25% potassium permanganate for 20 min followed by 3 min bleaching in 2% potassium metabisulphite and 1% oxalic acid. Sections were stained with 0.015% ThS in 50% ethanol in the dark for 10 min. After developing in two changes of 50% ethanol for 4 min each, images were captured with Olympus Fluoview FV10i microscope, and ThS-positive plaques were counted in three sections per mouse hippocampus.

**Measurement of Glycosphingolipids (GSLs)** - The extraction of GSLs from the culture cells and the exosomes, the enzymatic digestion of GSL-glycans with EGCase I and II (Takara Bio, Shiga, Japan), and the purification of glycans using glycoblotting were performed as described previously (12). Purified GSL-glycans were analyzed by MALDI-TOF MS using an Ultraflex II TOF/TOF mass spectrometer equipped with a reflector, which was controlled by the FlexControl 3.0 software package (Bruker Daltonics, Bremen, Germany). All spectra were obtained as positive ions and were annotated using the FlexAnalysis 3.0 software package (Bruker Daltonics). The glycan structures were then identified by online database SphinGOMAP© (http://www.sphingomap.org/).

**Quantification of Chol, SM, Cer, and PC** - Total lipids were extracted from the exosomes or N2a cells by adding chloroform/methanol (1:2, v/v). Levels of sphingomyelin (SM) and ceramide (Cer) were determined by electron ionization-mass spectrometry (TripleTOF™ 5600) coupling with PeakView software (AB SCIEX, Framingham, MA). Cer (C16:0, d18:1) and SM (C16:0, d18:1) were purchased from Avanti Polar Lipid (Alabaster, AL) and were used as standards. The amounts of phosphatidylcholine (PC) and cholesterol (Cho) were measured by a phosphatidylcholine assay kit (BioVision, Milpitas, CA) and cholesterol E-test kit (Wako), respectively.

**Proinflammatory cytokine ELISA** - The levels of proinflammatory cytokines, including tumor necrosis factor (TNFα), interleukin (IL)-6, IL-1β, and interferon (IFN)-γ were determined by ELISA (Multi-Analyte ELISAArray, Qiagen) according to the manufacturer's instructions. Briefly, each APP mouse hippocampus was homogenized in 4M guanidine-HCl buffer (pH 8.0) using an ultrasonic homogenizer (TAITEC, Saitama, Japan). After an incubation at room temperature for 3 h, the homogenates were further
diluted in 0.1%BSA/PBS, and centrifuged at 16,000g at 4°C for 20 min. The resulting supernatant were applied to the ELISA. All samples were handled in duplicate.

**Endoglycosylceramidase (EGCase) and sialidase treatment** - Exosomes (1 mg protein/ml) were incubated with 0.5U/ml EGCase II (Takara Bio Inc., Shiga, Japan) at 37°C for 15 h in PBS containing 20 mM HEPES (pH 7.4), or 1U/ml sialidase from *Clostridium perfringens* (Sigma) at 37°C for 16 h in 50 mM acetate buffer (pH 5.5). Each mixture was centrifuged at 100,000 g for 1 h. The resultant precipitates were resuspended in TBS or HBS buffer and used for further examination.

**Seed-free Aß preparation** - Seed-free Aß solutions were prepared essentially according to a published report (13).

**Aß binding assay** - PKH26-labeled exosomes (untreated or treated with EGCase) were plated on chamber slideglass (Thermo Fisher Scientific, Waltham, MA) by staying in PBS for 1 h at RT. Fluorescence-labeled Aß1-42 (1 µM) was then added into the chamber of cultured N2a cells or the labeled exosomes and co-incubated in serum-free medium at 37°C for 5 h. After a wash with PBS to remove free Aß, fluorescent images were captured using Olympus Fluoview FV10i microscope.

**Binding analysis by surface plasmon resonance (SPR)** - The binding studies of N2a-derived exosomes (untreated or pretreated with EGCase) with immobilized Aß peptide (Aß1-40, Aß1-42, Aß1-38 or Aß42-1) were performed using BIACORE T200 instrument (GE Healthcare). Briefly, seed-free Aß was independently immobilized onto a carboxymethylated (CM) dextran-coated gold surface (CM5 sensor chip) by amine coupling. The amount (RU) of immobilized Aß1-40, Aß1-42, Aß1-38 or Aß42-1 was 1143.0, 1266.7, 1316.3 or 948.0, respectively. Then the exosomes were suspended in HBS buffer (10 mM HEPES, 150 mM NaCl, pH 7.4) and injected over the surface at 25 °C for one minute at a flow rate of 30 µl/min. The resultant responses were subtracted from a blank that was immobilized with bovine serum albumin (BSA) or prepared by ethanolamine deactivation. Finally, the exosomes were regenerated from the Aß-immobilized surface by injecting 5 M guanidine-HCl, 10 mM Tris-HCl (pH 8.0).

**Thioflavin T (ThT) assay** - Seed-free Aß1-42 solutions (15 µM) were incubated at 37°C for various times with the exosomes (100 µg protein of exosomes in 100µl TBS), which had been untreated or treated with EGCase. Fluorescence intensities of ThT (Sigma) were determined as described before (8) using an Appliskan spectrofluorophotometer (Thermo Fisher Scientific).

**Exosome uptake assay** - Uptake of PKH26-labeled exosomes into microglial BV-2 cells were measured as described previously (8). Briefly, fluorescent exosomes were administered to BV-2 cells and incubated for various times in serum-free conditions. After a wash, the cells were then fixed, and confocal images were acquired using an Olympus Fluoview FV10i microscope. The fluorescence intensity of each samples was analyzed with ImageJ software.

**RESULTS**

**Exogenously injected exosomes trap Aß and are incorporated into microglia in mouse brains** - To explore the hypothesis that providing exogenous exosomes in vivo would enhance Aß clearance by facilitating engulfment of exosome-bound Aß by microglia, we loaded isolated exosomes into mouse brains and evaluated the effect on the balance of Aß metabolism. Exosomes were collected from culture supernatants of mouse neuroblastoma
Neuro2a (N2a) cells using sequential ultracentrifugation; the exosomes typically consisted of membrane vesicles of 70-120 nm in diameter (Fig. 1A and B) as previously described (14). The presence of exosomes was confirmed by detecting the exosomal markers Alix and flotillin-1 as well as the membrane glycolipid GM1 ganglioside, in sucrose density gradient fractions corresponding to a density of 1.12 and 1.16 g/ml (Fig. 1C). Aβ was not identified in N2a cells and the exosomes used in this study (Fig. 1C). Exosomes isolated from N2a cells were biotinylated and injected into the hippocampus of APPSweInd transgenic (APP) mice. Hippocampal Aβ was detectable in streptavidin-precipitated exosomes, together with the marker Alix, 3 h after the injection (Fig. 1D). Accompanied by Aβ, the intrahippocampal-injected exosomes co-localized with the microglial marker Iba1 (Fig. 1E), agreeing with our previous in vitro study (8). These results demonstrate that in mouse brains exogenous exosomes bind Aβ and are then incorporated into microglia, together with the bound Aβ, for degradation.

Continuous exosome administration ameliorates Aβ pathology and synaptic dysfunction in APP mouse brains - we next continuously administered exosomes into the lateral ventricles of 4-month-old APP mice for 14 days using osmotic minipumps. The exosome solution (2 mg protein/ml) contained 2.67×10^{12} particles/ml, which is ~35 times higher than the concentration of the exosomes in mouse cerebrospinal fluid (CSF) (7.51×10^{10} particles/ml). The intraventricularly injected exosomes have been reported to penetrate into brain parenchyma (15). After two weeks, there was an approximate 50% reduction in total Aβ1-40 and Aβ1-42 levels and 35% reduction in Aβ1-38 levels in the hippocampus of the exosome-treated APP mice, compared to those infused with vehicle (Fig. 2A). A similar decline in Aβ levels was confirmed by direct administration of the exosomes into mouse hippocampus, with ~50% less observed in the ipsilateral injection side than the contralateral (Fig. 2B). APP mice given vehicle treatment exhibited approximately 50% decreased densities in synaptophysin immunoreactivities in the hippocampus, as compared to wild-type mice (Fig. 2C and D), agreeing with previous reports (11). After a 14-day-infusion of the exosomes, the synaptophysin immunoreactivities were markedly increased in the APP mouse hippocampus (85% and 50% of those observed in WT mice, following exosome and PBS treatment, respectively; Fig. 2D). Thus, the exosomes mediated significant recovery from synaptic impairment in the APP mice. Taken together, these findings validated that in vivo, exogenously added exosomes induce reductions in Aβ levels and Aβ-associated synaptotoxicity.

To assess the effect of exogenous exosomes on brain amyloid deposition, we continuously administered the exosomes into the hippocampus of 13-month-old APP mice for 14 days. We found that the exosomes markedly decreased the Aβ immunoreactive burden (65% reduction; Fig. 3A and B) and number of thioflavin-S-positive plaques (38%; Fig. 3C) in the treated hippocampus, compared with the untreated side. Supporting these histological results, tissue levels of Aβ1-40 and Aβ1-42 were also significantly decreased following exosome infusion, as determined by ELISA (Fig. 3D). We also performed exosome infusion into the lateral ventricles of 13-month-old APP mice for 14 days and found significant reductions in Aβ1-40 and Aβ1-42 levels in the mouse hippocampus (Fig. 3E). These findings demonstrate the evident efficacy of long-term treatment with exogenous exosomes in Aβ deposition, even deposition of the fibrillar species of Aβ aggregates, in APP mice.
To exclude the possibility that the changes observed in vivo are due to effects of exosomes on Aβ generation and enzymatic degradation, we examined the expression levels of APP and its cleaved fragments, including CTF-α and CTF-β, in the hippocampus. No obvious differences in the expression levels were apparent between the exosome- and PBS-treated APP mice (Fig. 4A). In addition, the expression levels of well-known proteases for Aβ peptides, including insulin-degrading enzyme (IDE), neprilysin (NEP), and angiotensin-converting enzyme (ACE), were investigated, but there were no variations even after exosome infusion (Fig. 4A). Although the exogenous exosomes were taken up by the microglia, there was no obvious activation in releasing the proinflammatory cytokines like tumor necrosis factor α (TNFα), interleukin (IL)-6, IL-1β, or interferon (IFN)-γ in the exosome-treated mouse hippocampus (Fig. 4B). The above findings indicate that the exosomes reduce Aβ levels by promoting an alternative pathway for Aβ clearance, i.e., exosome-associated Aβ uptake by microglia, without any stimulation in APP processing, Aβ degradation, or microglial inflammatory reactions.

Exosomal GSL-glycans are critical for their association with Aβ in vitro and in vivo - The above experiments clearly indicate that the exogenous exosomes associated with the Aβ in the mouse brains, although how they interact with each other remained to be determined. Increasing evidence with synthetic liposomes or membranes has demonstrated that gangliosides (sialic acid-containing GSLs) clustering on the membrane surface bind to Aβ, and that this Aβ-GSL complex then acts as a template for catalyzing the reaction of Aβ fibril formation (16,17). In vivo, the monosialoganglioside GM1 was found to associate with Aβ in human brains that exhibit AD pathology (18,19). GSLs are reported to exist in exosomes (6), but details regarding which species of GSLs have not yet been described. We summarized the profiles of GSL-derived glycans from the exosomes and the cells from which the exosomes derived, by quantitative GSL-glycomics (Table 1). The total amount of GSLs was much higher in exosomes than in the parent cells (~2,300%, Fig. 5A). In either, the vast majority of GSLs were GM2 (>84%), with distinct minor compositions (Table 1). Except for GM2, the levels of sialylated GSLs were much higher in the exosomes (Fig. 5B). To investigate whether the GSLs abundant in the exosomes might affect Aβ binding and fibril formation, we deglycosylated exosomal GSLs using endoglycoceramidase (EGCase), which specifically cleaves the linkage between the oligosaccharide and glucosylceramide in GSLs (20). The particle size of the exosomes was stable up to 5 h after EGCase digestion, though larger aggregates commonly formed during the 24 h-incubation (Fig. 5C). Within the 5 h-period, the EGCase-treated exosomes associated very little with the Aβ, as compared to intact exosomes, which overtly colocalized with the Aβ (Fig. 5D).

We performed surface plasmon resonance (SPR) studies to evaluate the specificity of the interaction between N2a-derived exosomes and individual Aβs. As shown in Fig. 5E, when the exosomes were injected onto the immobilized Aβ1-42 and Aβ42-1, a peptide with reverse sequence of Aβ1-42, only the former gave a significant increase in resonance signal, demonstrating the specific nature of the interaction. Specific interactions of the exosomes were observed not only with immobilized Aβ1-42 but also with Aβ1-40 and Aβ1-38, and we found that the interactions were almost completely diminished when the exosomes were pretreated with EGCase (Fig. 5F). These results suggest that Aβs directly bind to the exosomes through the GSL glycans, particularly
those sialic acid moieties on their surface. Pre-treatment with EGCase also inhibited exosome-dependent amyloid fibril formation in incubation mixtures of exosomes and Aβ1-42, as assessed by thioflavin-T assay and electron microscopic observation (Fig. 6A and B). Cleavage of sialic acids with sialidase resulted in similar reductions in fibril formation (Fig. 6C). Steric blocking of GM1 or GM2 ganglioside by cholera toxin subunit B (CTB) or anti-GM2 antibody, respectively, also partially but significantly suppressed amyloid formation (Fig. 6C). In contrast to intact exosomes, the EGCase-treated exosomes nearly failed to coprecipitate with Aβ when injected into the hippocampus of APP mice (Fig. 6D). Our data verify that cleavage of GSL glycans from exosomes can sufficiently prevent the association of exosomes with Aβ. This suggests that there may be multiple species of GSLs, especially sialylated forms, on exosomal membranes that organize into unique sites of high potency able to induce Aβ binding and assembly.

In addition to gangliosides, cholesterol and sphingomyelin (SM) are also known to promote Aβ assembly via the lateral packing of gangliosides on membranes (21,22). We found that both cholesterol and SM were highly abundant in exosomes compared with their parent cells (Fig. 7), suggesting that high densities of these two lipids would promote GSL binding to Aβ. Another lipid, ceramide (Cer), which is the hydrophilic backbone of GSLs, is known to be involved in exosome generation (23). We found higher levels of ceramide in exosomes than in cells (Fig. 7), consistent with a previous report (23).

**Exosomes are incorporated into microglia in vitro and in vivo, in a GSL-glycan-independent manner** - Our previous in vitro experiments demonstrated that engulfment of exosomes by mouse primary microglia occurred in a partially phosphatidylserine (PS)-dependent manner (8). However, deglycosylated proteins, e.g. immunoglobulin FC receptor, reportedly exhibit low affinity towards microglia (24). To determine whether cleavage of GSL-glycans would affect microglial uptake of exosomes, we exposed fluorescent-labeled exosomes pretreated with EGCase or PBS, to microglial BV-2 cells. We found no decrease in microglial uptake of EGCase-treated exosomes (Fig. 8A). Both of the labeled exosomes were co-localized with the microglial marker Iba1 when intracerebrally injected into mouse brains (Fig. 8B), and there were no obvious differences observed between untreated or EGCase-treated exosomes. Few fluorescent exosomes were apparent in merged images of cells stained for either a neuronal or astroglial marker (Fig. 8C). The above data indicate that exosomes can be incorporated into microglia undisturbed by the absence of GSL-glycans on the membrane.

**DISCUSSION**

Our study presented here clearly demonstrated that intracerebral exosome infusion leads to a decrease in Aβ levels and ameliorates Aβ-related pathologies in APP mice. In the mouse brains, Aβ was trapped at the exosome surface by glycan moieties of GSLs and transported into microglia for degradation. Mass spectrometry-based analysis has revealed that GSLs are abundant in exosomes, compared to parental cells. Just how GSLs are packed so much more into the exosomes than in parental cells remains an unanswered question. Exosomes are produced by intraluminal budding of the limited membrane of endosomes. Accumulation of Cer, which is generated by the hydrolysis of SM, has been reported to initiate the budding (23). Cer can induce a coalescence of...
small microdomains into larger microdomains to drive domain-induced budding of biological membranes (25), which results in highly loading Cer and its vicinal lipid molecules into the generated vesicle. Indeed, Cer and SM are concentrated in exosome membranes (Fig. 7) (23). In addition, SM forms a distinct membrane domain, namely a lipid raft, in the plasma membrane together with GSLs and cholesterol (26). Various raft-resident proteins have also been reported to be abundant in exosomes (27).

In the present study, providing GSLs-enriched exosomes to the APP mouse brains resulted in recovering synaptic impairment and decreasing Aβ plaques. However, the effect of GSLs on AD pathogenesis is a controversial issue. GSL storage disorders, which are subtypes of lysosomal storage diseases caused by genetic dysfunction in GSL catabolism, share pathological features with AD, such as Aβ burden (28,29). Accumulated gangliosides are observed in human brains exhibiting AD, and they are proposed to contribute to AD development through promoting Aβ fibril formation (16). These discrepant effects of GSLs are likely to stem from their life span in brain tissues. Pathologically accumulated GSLs are pooled within cells to form complexes with Aβ and its polymer (19,28), which might be retained to exert neuronal damages. On the other hand, exosomal GSLs capture Aβ in extracellular fluid and are rapidly taken up by phagocytes without persistent harm to the brain.

Our present study demonstrated that exosomes derived from N2a cells can promote Aβ fibril formation on their surface (Fig. 6A and B). The exosome-bound Aβ was then incorporated into microglia for degradation (Fig. 1E, Fig. 8A and B)(8). Therefore, continuous infusion of exosomes induced a reduction in amyloid depositions in aged APP mouse brains (Fig. 3C). These results provide a notion that the exosomes in the brains are rapidly cleared by microglia before the exosome-bound Aβs form amyloid fibrils for depositions. Amyloid plaques were reported to change their sizes over days in the brains of AD model mice (30). The exogenously added exosomes might prevent further Aβ depositions by blocking the supply of the soluble Aβ. Alternatively, exosomes might support the clearance of amyloid deposit, which already formed. The complex of GM1-Aβ has reported to localize at the ends of extended Aβ fibrils in the incubation mixture of GM1 and Aβ (19). Alix, a marker for exosomes was enriched around the small Aβ plaques in brain sections from AD patients (6). Similarly, once the exogenous exosome-associated Aβs are attached to the Aβ fibrils in the amyloid plaques, they might provoke microglia gathering toward the plaques and accelerate their clearance.

Here, we used seed-free Aβ to perform the Aβ binding assay (Fig. 5D) and the SPR analysis (Fig. 5E and F) and demonstrated that Aβs directly bind to the exosomes through the GSL glycans on their surface. Seed-free Aβ was reported to contain soluble species of Aβ, but not insoluble amyloid forms (13). The GM1-Aβ complex, which acts as a seed for Aβ amyloidgenesis, is known to consist of a clustered GM1 and a monomeric Aβ molecule (17, 31). Accordingly, our previous report have demonstrated that the exosomes derived from N2a cells almost prevented the oligomeric Aβ formation from seed-free Aβ, but not those preformed Aβ oligomers, which are recognized by A11, a specific antibody against oligomer (8). Thus, the above findings suggested that the exosomes released from N2a cells would be mostly associated with monomeric Aβ through their surface GSLs. However, a recent study demonstrated that soluble Aβ oligomer strongly binds to GM1-containing membranes in vitro and in vivo, and GM1-bound Aβ is detected in human
CSF (32). An additional investigation may be required in future to clarify which form of Aßs can be associated with the exosomes.

It is worth noting that other aggregate-prone proteins, including α-synuclein and prion protein, which cause Parkinson’s and Creutzfeldt-Jakob diseases, respectively, are also associated with exosomes (33,34). In addition, α-synuclein and prion protein have been reported to associate with GSLs on the surface of synthetic liposomes (35,36). A challenging subject of future studies will be determining whether exosomes are involved in the clearance of these proteins.

The normal phagocytic function of microglia is conceivably important for exosome-bound Aß clearance in this study. Increasing evidence has indicated that a large portion of secreted exosomes are convincingly taken up by microglia (8,37). In contrast, small amount of exosomes can be incorporated into neurons (38). If the clearance function of microglia is decreased or absent, then the exosome-bearing aggregate-prone proteins would trigger pathological events (i.e., formation of senile plaque) or even perform minor interneuronal transfer to propagate their toxic assemblies. Indeed, exosome-associated prion proteins, in which their folded species are infectious, can spread between neuronal cells in a monoculture system (33). The transmissibility of amyloids, a characteristic feature of many neurodegenerative diseases including Alzheimer disease and spongiform encephalitis, might emerge under a lack of glial activity for removing exosomes.

Improvement of Aß clearance by exosome administration or enhancement of exosome generation provides a novel therapeutic approach for AD therapy. It is noteworthy that the Aß-degrading enzymes, IDE and neprilysin, have been reported to be found in exosomes secreted from microglia and adipose tissue-derived mesenchymal stem cells, respectively (39,40). Exosomes have been used as a delivery platform, encapsulating reagents or siRNAs (41,42). Peripheral injection of the exosomes holding siRNA (against an APP processing enzyme, BACE1) succeeded in brain targeting and specific gene knockdown in mice (41). In the future, development of engineered nanovesicles that regulate multiple processes in AD pathogenesis might be a valuable tool for the therapy.

FIGURE LEGENDS

FIGURE 1. Exogenously injected exosomes trap Aβ and are internalized into microglia in mouse brains. Exosomes were isolated from culture supernatant of N2a cells by sequential centrifugation, eventually to 100,000g pellets. A. An electron microscopic image of phosphotungstic acid-stained exosomes. B. Exosomes were measured by dynamic light scattering. C. Exosomes were density-fractionated by sucrose gradient, and the fractions were analyzed by Western blotting to detect the exosome markers Alix, flotillin-1 (Flot-1), and ganglioside GM1 (GM1), as well as actin and Aβ. CL; cell lysates. D. Biotinylated exosomes stereotaxically injected into the hippocampus of 4-month-old non-transgenic or APP mice were isolated using biotin-binding affinity beads, then analyzed by Western blotting to detect co-precipitated full-length (FL)-APP, Aβ, and Alix. E. Conjugates of fluorescence-labeled Aβ (green) and exosomes (red) were administered into the hippocampus of non-transgenic mice. The hippocampal images were captured 3 h after the injection, following antibody staining for the microglial marker Iba1 (blue). Scale bar, 50 µm and 10 µm (inset).

FIGURE 2. Intracerebral administration of N2a-exosomes induces Aβ clearance. Exosomes (12 µg protein/PBS/day) or vehicles were continuously infused into lateral ventricle (A, C, D) or right hippocampus (B) of APP mice (4 months) for 14 days. A. After the infusion, hippocampal levels of Aβ were measured by enzyme-linked immunosorbent assay (ELISA). (n≥5 animals per group; mean ± SD, *p<0.05, **p<0.01; Student's t test). B. Hippocampal Aβ levels in ipsilateral and contralateral side were measured by ELISA. Values are represented as percentages of the Aβ levels in the contralateral side. (PBS: n=3, exosome: n=4; mean ± SD, **p<0.01; Student's t test). C. Representative hippocampal sections of exosome- or vehicle-infused APP mice or age-matched nontransgenic controls, stained with
antibody against synaptophysin. MoDG, molecular dentate gyrus (DG); GrDG, granular DG; PoDG, polymorph DG. Scale bar, 100 µm. D. Densities of synaptophysin-positive presynaptic terminals in the hippocampal sections in (C) were quantified (5 sections/mouse, 5 mice per group). Data presented are the mean±SD, ***p<0.001.

FIGURE 3. Intracerebral administration of N2a-exosomes reduces Aß deposition. Exosomes (12 µg protein/PBS/day) were continuously infused into the hippocampus (A-D) or lateral ventricle (E) of 13-month-old APP mouse for 14 days. A. Representative image of APP mouse hippocampal section stained with antibody against Aß (4G8). DG, dentate gyrus. Scale bar, 200 µm. B. Aß-immunopositive areas in each hippocampal region were quantified. (n = 4 animals, three or four sections per mouse brain; ***p<0.001). C. The number of ThS-positive plaques in each hippocampus was determined. (n = 4 animals, two or three sections per a brain; *p<0.05). D. The levels of hippocampal Aß1-40 and Aß1-42 were measured by ELISA. (n= 3 animals, assayed in duplicate; **p<0.01). E. Exosomes (Low, 12 µg protein/PBS/day; High, 24 µg protein/PBS/day) were infused. Hippocampal Aßs were measured by ELISA. (n≥4 animals per group; **p<0.01 compared to PBS).

FIGURE 4. Exogenous exosomes do not stimulate APP processing, expressions of Aß-degrading enzymes, or inflammatory response. Exosomes or PBS were continuously infused into the lateral ventricles of APP mice (4-month-old) for 14 days (A and B). n≥5 animals per group. A. Full-length (FL)-APP, APP-C-terminal Fragments (CTFs), and the Aß-degrading enzymes insulin-degrading enzyme (IDE), neprilysin (NEP), and angiotensin-converting enzyme (ACE) were detected in the hippocampus by Western blotting, and the intensity for each band was quantified. Data presented are the mean ± SD. B. Expression levels of proinflammatory cytokines (IL-1ß, IL-6, IFN-γ, and TNF-α) in the hippocampus were measured by ELISA. Data are mean ± SD.

FIGURE 5. Exosomal GSLs are responsible for Aß binding on the vesicles. Exosomal and cellular glycomes of GSLs were surveyed by mass spectrometry. A. Total amounts of GSL-glycans in exosomes and their originating cells were determined by standardization with protein or phosphatidylcholine (PC) content. B. GSLs other than GM2 detected in exosomes or cells were classified according to the number of sialic acid moieties. C. Particle size of exosomes (untreated or treated with EGCase) was determined by dynamic light scattering analysis after incubating them at 37°C for 0, 5, and 24 h. D. Representative images of Aß binding on N2a cells and exosomes (untreated as Ctrl, or treated with EGCase, red) after 5 h incubation with fluorescent Aß1-42 (1 µM, green). The cells were stained with DAPI. Arrows indicate Aß fluorescence co-localized with exosomal signals. Scale bar, 25 µm (N2a cells) and 10 µm (exosomes) E. Surface plasmon resonance sensorgrams showing the interactions of N2a-derived exosomes (1 µg protein/µl) with immobilized Aß1-42 or Aß42-1. The responses were subtracted from a blank surface prepared by ethanolamine deactivation F. Sensorgrams showing the interactions of the exosomes (untreated ctrl, or pretreated with EGCase, 1 µg protein/µl) with immobilized Aß1-40, Aß1-42, or Aß1-38. The resultant responses were subtracted from a surface that was immobilized with bovine serum albumin (BSA).
FIGURE 6. **Exosomal GSLs are involved in Aβ assembly.** *A.* Thioflavin fluorescence intensities were measured in mixtures of exosomes (untreated as Ctrl, or treated with EGCase) incubated with 15 µM Aβ1-42. Data are presented as the mean ± SD, ***p<0.001 (n=4). *B.* Representative electron microscopic images of exosomes incubated for 5 h with 15 µM Aβ1-42 are shown. Scale bar, 100 nm. *C.* The exosomes (untreated as Ctrl, or treated with EGCase or sialidase) were incubated for 5 h with 15 µM Aβ1-42. The untreated exosomes were reacted with Aβ in the presence of cholera toxin B subunit (CTB) or anti-GM2 antibody. Fluorescence intensities of thioflavin-T were then measured. Values in each column are the mean ± SD of five values. *p<0.05, **p<0.01. *D.* Biotinylated exosomes (untreated as Ctrl, or treated with EGCase), stereotaxically injected into the hippocampus of APP mice (4 months), were isolated at 3 h after the injection, and the levels of exosome-associated Aβ were quantified by ELISA. Values are the mean ± SD (n=4).

FIGURE 7. **Exosomal and cellular lipid analysis.** Levels of phosphatidylcholine (PC), cholesterol (Chol), sphingomyelin (SM), and ceramide (Cer) were measured in N2a cells and the isolated exosomes. The data presented are mean ± SD from three independent experiments; *p<0.05, **p<0.01, ***p<0.001.

FIGURE 8. **Cleavage of exosomal GSL-glycans does not affect their uptake by microglia.** *A.* Fluorescence-labeled exosomes (untreated as Ctrl, or treated with EGCase) were exposed to microglial BV-2 cells for 3 h, and the fluorescence intensities of exosomes taken up into the cells were determined by confocal microscopy. *B.* Representative hippocampal sections of non-transgenic mice (4 months) injected with fluorescence-labeled exosomes (untreated as Ctrl, or treated with EGCase, red) and stained with anti-Iba1 antibody. Arrows indicate significant exosomal fluorescence in Iba1-positive microglia. Scale bars, 50 µm and 10 µm (inserts). *C.* Hippocampal sections from non-transgenic mice (4-month-old) injected with fluorescence-labeled exosomes (untreated as Ctrl, or treated with EGCase) stained with antibodies against the neuronal marker βIII tubulin or the astroglial marker glial fibrillary acidic protein (GFAP). Bar, 50 µm.
