Abstract
Elevated amyloid-β peptide (Aβ) in brain contributes to Alzheimer's disease (AD) pathogenesis. We demonstrated the presence of exosome-associated Aβ in the CSF of cynomolgus monkeys and APP transgenic mice, which notably decreased in aging animals. We also determined that neuronal exosomes, but not glial exosomes, had abundant GSLs and could capture Aβ. Infusion of neuronal exosomes into brains of APP transgenic mice decreased Aβ and amyloid depositions, similar to previous reports of neuroblastoma-derived exosomes. These findings highlight the role of neuronal exosomes in Aβ clearance, and suggest their downregulation might relate to Aβ accumulation, which serves to develop AD pathology.

Keywords
Exosome, Amyloid-β peptide, Alzheimer's disease, Cynomolgus monkey, APP transgenic mouse, Cerebrospinal fluid

Abbreviations
Aβ, amyloid-β peptide; AD, Alzheimer disease; APP, amyloid-β precursor protein; GSL, glycosphingolipid; CSF, cerebrospinal fluid; N2a, Neuro2a; EGCase, endoglycoceramidase
Introduction

A pathological feature of Alzheimer's disease (AD) is the presence of senile plaques, extracellular amyloid depositions of amyloid-β peptide (Aβ). Aβ is generated by the processing of amyloid precursor protein (APP), and is maintained at a steady state in normal brain. However, disruption of the balance in Aβ metabolism contributes to the formation of toxic Aβ assemblies and amyloid depositions, which are linked to AD pathogenesis. Recently, exosomes, a subtype of secreted vesicles, were reported to associate with extracellular Aβ in cultures of APP-expressing neuroblastoma cells [1, 2]. Similarly, our previous study both in vitro and in vivo demonstrated that exosomes released from neuroblastoma N2a can bind Aβ on their surface glycosphingolipids (GSLs) and these Aβ-bound exosomes are then internalized by microglia for degradation [3, 4]. This suggests that N2a-derived exosomes may act for Aβ elimination in brain. However, it remains unclear whether the exosomes, which originate from cells resident in the central nervous system, also contribute to Aβ metabolism.

Materials and Methods

Animals.

Wild type C57BL/6 mice and mice expressing the human APP bearing the Swedish and Indiana (KM670/671NL, V717F) mutations (J20) were obtained from SLC Inc. (Hamamatsu, Japan) and the Jackson Laboratory (Bar Harbor, ME), respectively. All animal procedures were approved by the Animal Care Committees of Hokkaido University.

Monkey and murine samples

Cynomolgus monkeys (Macaca fascicularis) were housed at the Tsukuba Primate Research Center (TPRC), National Institute of Biomedical Innovation (NIBIO), Ibaraki, Japan. Monkey CSF samples were obtained by lumbar puncture. Nine CSF samples were from young monkeys (4-8 years old), 8 from adult monkeys (11-21 years old), and 4 from aged monkeys (24-36 years old). Each CSF sample was used for exosome isolation without prior freezing. The parietal lobes of 20 monkeys were used for Western blotting and ELISA. All animals were bred and maintained in an air-conditioned room at the TPRC with controlled illumination (12 h light/12 h dark), temperature (25 ± 2°C), humidity (60 ± 5%), and ventilation (10 cycles/h), and were
given 70 g of commercial food and 100 g of apples daily, with unlimited access to tap water [5]. The maintenance of animals was conducted according to rules of the TPRC at NIBIO regarding the care, use, and biohazard countermeasures of laboratory animals. All animal experiments were conducted according to the guidelines of the Animal Care and Use Committee of the NIBIO, Japan.

Mouse CSF was sampled from the cisterna magna following protocols previously reported [6]. Each 50 µL of CSF was collected from 2-month-old C57BL/6 mice or APP mice at the indicated ages.

Cell cultures.

Primary neuron cultures were prepared from the cerebral cortices of mouse brains on embryonic day 15 as described previously [3]. Primary glial cultures were prepared from the mouse cortex according to published methods with minor modifications [7, 8]. Briefly, the neocortex was removed from each 2-day-old mouse pup, dissociated in a dissociation solution (Sumitomo Bakelite, Tokyo, Japan), and plated in DMEM and 10% fetal bovine serum (FBS). After being cultured for 14 days, the microglia were detached by shaking, and the separate cells were cultured in DMEM/5% FBS. The astrocytes remaining in the flasks were cultured in DMEM/10% FBS. The resultant glial cells were cultured for two days and used for further analysis.

Exosome isolation.

Exosomes were prepared from supernatants of primary cultures as described previously [3]. Briefly, after culture of cells for one day, the culture supernatants were sequentially centrifuged at 2,000g for 10 min, and at 10,000g for 30 min, and at 100,000g for 1 hour to obtain exosomes as pellets. Using this same method, exosomes were also isolated from the CSF samples of APP mice or monkeys.

Electron microscopy.

Exosomes were stained with phosphotungstic acid. For immunolabeling, the exosomes were incubated with anti-Ab antibody (4G8) then 10 nm gold-coupled anti-IgG. Images were taken with JEM-ARM200F (JEOL Ltd., Tokyo, Japan) transmission electron microscope.
Western Blotting.

To detect target proteins, we employed monoclonal antibodies against Alix, GM130, Transferrin receptor (BD Biosciences), and Aβ (6E10, Signet, Dedham, MA), and a polyclonal antibody against flottilin-1 (Santa Cruz Biotechnology). Ganglioside GM1, was detected by cholera toxin B subunit (Sigma).

Fluorescence labeling for the exosomes.

Labeling of the exosomes was performed using PKH26 (Sigma) as described previously [3].

Analysis of particle size and number.

The exosomes collected from primary cultures of neurons and CSF samples were suspended in PBS, and a qNano System (Izon Science, Ltd) employed to analyze the particle size and densities. CPC100 was used as the calibration sample.

Exosome administration into mouse brains.

The experiment was performed as previously described [4]. Briefly, mice were continuously treated with exosomes (2 mg protein/ml) or PBS by Alzet minipump at 0.25 µl/h for 14 days. The Brain Infusion Kit were implanted into the right hippocampus using a stereotactic instrument. One hemibrain was fixed for immunohistochemistry, and the other was frozen for use in ELISA.

Immunohistochemistry and thioflavin-S (ThS) staining

Immunostaining and ThS staining were performed as described previously [4].

Aβ ELISA.

Aβ1-40 and Aβ1-42 levels were determined using an ELISA kit (Wako, Osaka, Japan) as previously described [4].

Measurement of Glycosphingolipids (GSLs).

Levels of GSLs in the exosomes of primary cultures were measured as described previously [4]. After their extraction, the GSLs were enzymatically digested with EGCase I and II, further purified by glycoblotting, then analyzed by MALDI-TOF MS.
**Endoglycosylceramidase (EGCase)**

Exosomes (1 mg protein/ml) were incubated with 0.5U/ml EGCase II (Takara Bio Inc., Shiga, Japan) at 37°C for 15 h in PBS.

**Thioflavin assay**

Thioflavin-T (ThT) assay was performed as previously published [4].

**Aβ binding assay.**

Fluorescent Aβ\textsubscript{1-42} (25 µM) was incubated with the PKH26-labeled exosomes (treated with or without EGCase) in serum-free medium at 37°C for 5 h. The exosomes and bound Aβ were observed after wash out free Aβ.

**Results**

**Exosomes associate with Aβ in the CSF of non-human primates.**

The nonhuman primate cynomolgus monkey is widely used for AD-related preclinical studies [9]. In the monkey brains, Aβ naturally increases in an age-dependent manner (Fig. 1A) as described in the previous reports [10, 11]. To investigate the effect of exosomes originating from brain cells against Aβ metabolism, we isolated exosomes from monkey CSF, then measured the Aβ levels in the exosome fractions. The CSF-derived exosomes were confirmed by electron microscopy to mainly consist of small membrane vesicles 50-200 nm in diameter (Fig. 1B), similar to previously described [12]. The exosome size was further verified by a nanoparticle analyzer, which found the sizes to range from 100 to 200 nm (Fig. 1C). The exosomal markers were also identified in the CSF-exosome fractions (Fig. 1D). We found that Aβ was detectable in all CSF-derived exosome fractions but that the levels of exosome-associated Aβ were markedly lower in the adult and aged brains compared to the young subjects (Fig. 1E). The level of free Aβ, which was not associated with the exosomes in the CSF, declined only in the aged brains (Supplemental Fig. 1). These results suggest that the function of exosomes transporting Aβ in the central nervous system may deteriorate with age (>11-year-old).

**Age-related alterations in the number of exosomes in primary neuronal cultures and**
**APP transgenic mouse CSF.**

Neuronal cell cultures are widely used as models to study the molecular mechanisms of aging. We collected the exosomes from primary cultures of cortical neurons at 1, 7, or 14 day in vitro (DIV) and found that there were significant reductions in the number of particles at DIV14 compared to those at DIV1 or DIV7 (Supplemental Fig. 2A). While exosomal GSLs, especially sialylated GSLs, kept rising up to DIV14 (Supplemental Fig. 2B). These suggest that a reduction in exosome release might occur during aging, with maintaining the capacity of individual exosome to bind with Aβ.

To investigate whether the above findings in the non-human primates and in the neuronal cultures are also observed in APP transgenic mice, we collected the exosomes from CSF of 13-month-old APP mice and examined them for the presence of Aβ, using western blot analysis and electron microscopy with immunolabeling (Fig. 2A, B). We then quantified the exosomes isolated from APP mouse CSF at ages 2 to 23 months. Compared to the number of CSF-exosomes isolated from young mice (2-3 months old), the densities of exosomes in mice aged 6-7 months decreased; these low levels were maintained through 12-13 months of age, thereafter drastically declined in 23-month-old mice (Fig. 2C). We also showed marked reduction in Aβ levels in the CSF-exosomes between 2- and 23-month-old APP transgenic mice (2.19 ± 0.36 nM and 0.015 ± 0.012 nM, respectively), in accordance with those in the monkey CSF with age. In contrast, Aβ levels in the brain tissues continued rising in mice from ages 6-7 months to 23 months. The above data raised the possibility that endogenous exosomes released from brain cells may play a role in modulating Aβ metabolism.

**GSL-enriched neuronal exosomes, but not glial exosomes, associate with Aβ.**

We previously determined that the enriched glycans of the GSLs are essential for Aβ binding and assembly on N2a-exosomes [3]. To examine this in our current model, we collected exosomes from primary cultures of rodent cortical neurons, astrocytes and microglia, and determined the profiles of their GSL-derived glycans and their propensity for trapping Aβ. We found that there were significantly more GSLs in neuronal exosomes than in exosomes from glial cells (Fig. 3A). Sialylated GSLs were also abundant in the neuronal exosomes; in particular, trisialoganglioside GT1 was found in only neuronal exosomes (Supplemental table. 1). Ganglioside GM1, which has been reported to bind Aβ in AD brains, was also highly enriched in neuronal exosomes.
(Supplemental Fig. 3 and table). Accordingly, neuronal exosomes, but not glial exosomes, associated with Aβ (Fig. 3B). In ThT assays for amyloid fibril detection, fluorescence intensities were enhanced after a 5 h-incubation with Aβ (Fig. 3C). Pretreatment of the neuronal exosomes with EGCase largely prevented the ThT fluorescence (Fig. 3C), indicating that the GSLs abundant in the neuronal exosomes contributed to the potency of the exosomes to bind Aβ.

**Administration of neuronal exosomes decreases Aβ pathology in APP mouse brains.**

To assess the effect of the exosomes derived from primary neurons on amyloid pathology, we continuously administered the exosomes into the right hippocampus of 13-month-old APP mice. We found that the exosomes induced marked reductions in Aβ immunoreactive burdens (Fig. 4A, B) and ThS-positive plaques (Fig. 4C) in the treated hippocampus. Tissue levels of Aβs were also significantly decreased following the exosome infusion (Fig. 4D). These findings demonstrate that the treatment with neuronal exosomes effectively ameliorates Aβ pathology in APP mice, suggesting a novel role for neuronal exosomes in clearing Aβ in brain.

**Discussion**

Our study shown here demonstrated that exosomes are presented in monkey and murine CSF. The exosomes collected from monkey CSF at all ages contained Aβ (Fig. 1E), demonstrating that endogenous exosomes are also coupled with Aβ. In addition, the numbers of exosomes in the CSF of APP transgenic mice changed in an age dependent manner (Fig. 2C). It remains unclear which age-related factors would modulate exosome numbers, although the impairment of endocytic transport might be a potent possibility. Endocytic disturbances, such as endosome enlargement, are observed in aged monkey brains, with concomitant higher expression of Rab GTPases, which are responsible for the endosome transport [13, 14]. In addition, the dysfunction of dynein, a microtubule-associated protein active in endosome trafficking, has also been observed in aged monkey brains [13]. Notably, knockdown of dynein reduced exosome release from N2a cells [13]. Considering the appearance of endocytic pathology in early AD pathogenesis [15, 16], disturbance of intracellular transport might mediate the reduction of exosomes, eventually leading to Aβ accumulation in the aged brains.

Our study reported here clearly demonstrated that intracerebral infusion of neuronal
exosomes results in decreases in Aß levels and amyloid deposition in the brains of APP transgenic mice (Fig. 4). It is noteworthy that another pathological agent of AD, tau, can be collected from the CSF-exosomes of early AD patients [17], raising the possibility that exosomes modulate multiple factors associated with AD pathogenesis. The improvement of endogenous exosome generation might serve as a novel approach for treating or preserving AD.

Supplemental Information

Materials and Methods

Thin-layer chromatography

Total lipids of the exosomes (1 mg protein) were extracted in chloroform/methanol/water (10 : 5 : 3 by volume). The upper phase was removed and the solvent was evaporated and solubilized in chloroform/methanol (2 : 1 by volume). Total volume of lipid extract was spotted onto high performance thin-layer chromatography plates (Merck, Darmstadt, Germany) and separated with a solvent (chloroform/methanol/0.2% CaCl₂, 55 : 45 : 10). After the separation, the plates were thoroughly dried and coated with 0.1% polyisobutylmethacrylate/n-hexane for 1 min. The plate was overlaid with 1% bovine serum albumin/PBS buffer for 20 min at room temperature and then with primary antibodies at 4 °C overnight. After washing with PBS buffer containing 0.05% Tween 20, GM1, GM3, and GD1b were then visualized with horseradish-peroxidase-conjugated cholera toxin B subunit (CTB, Sigma-Aldrich, St. Louis, Missouri, USA), and antibodies specific to GM3 (Nippon Bio-Test Laboratories Inc., Tokyo, Japan), or GD1b (kindly provide by Dr. Robert K. Yu, Department of Neuroscience and Regenerative Medicine, Medical College of Georgia, Georgia Regents University), respectively.
