Abstract

Purpose: The purpose of the present study was to evaluate the effect of dexmedetomidine (DEX) on hippocampal synaptic activity *in vivo*.

Methods: The adult rats used for this study received a bolus intraperitoneal injection of 3, 10, 30, or 100 µg/kg of DEX or an equivalent volume of saline. Electrophysiological recording from the hippocampal CA1 region was initiated 20 min after drug administration. The results are expressed as the percentages of the population spike amplitude (PSA) measured just before high-frequency stimulation (HFS). The electrophysiological data were analyzed with an area under the curve (AUC) of 10–60 min after HFS. Moreover, to investigate the sedative dose of DEX rats, we recorded the duration of loss of spontaneous movement after the administration of each dose of DEX.

Results: Intraperitoneal administration of DEX at doses of 30 and 100 µg/kg induced a range of sedative effects. AUC measurements were significantly lower in the 30 and 100 µg/kg groups when compared to the vehicle rats (vehicle: 8.81 ± 0.49 , $n = 7$; DEX 30 µg/kg: 6.02 ± 0.99 , $n = 6$; DEX 100 µg/kg: 5.10 ± 0.43 , $n = 5$; $P < 0.05$).

Conclusion: Our *in vivo* study revealed that sedative doses of DEX impair the induction of hippocampal long-term potentiation (LTP). These findings may signify a causal link between DEX-induced sedative action and hippocampal LTP suppression, providing a better understanding of the mechanisms underlying the DEX-induced sedative and/or amnestic effect.

Introduction

Dexmedetomidine (DEX) is a potent, highly selective alpha-2-adrenergic agonist [1] that has both sedative and analgesic effects. DEX, which is an α_{2A} agonist, has several clinical advantages over other commonly used anesthetics with gamma-aminobutyric acid (GABA)-ergic and/or glutamatergic properties. For example, DEX induces sedation with minimal respiratory suppression. In addition, DEX-induced sedation is easily reversed with verbal or physical stimuli. Accordingly, recent reports indicate that the use of DEX as a primary sedative in critical care and as the sole anesthetic for certain surgical cases is expanding [2, 3].

Similar to other anesthetic agents, DEX has a potent amnestic effect. For example, Ebert et al. found suppression of recall and recognition memory after treating patients with sedative doses of DEX [4]. Further, DEX was reported to impair memory even at a low dose [5]. It is unclear how and where in the brain DEX acts to impair memory; however, a recent study using functional magnetic resonance imaging showed that DEX inhibits hippocampal activity in a region-specific fashion during learning [6]. Given that the hippocampus is crucially involved in learning and memory functions, these results led us to postulate that DEX acts on hippocampal functions.

The electrophysiological profile of DEX in the hippocampus has not been well characterized. Several studies have investigated the influence of DEX on hippocampal long-term potentiation (LTP), a mechanism involved in information storage during learning and memory [7]. For instance, Takamatsu et al. [8] showed that DEX impairs LTP induction in area CA1 of mouse hippocampal slices. However, no report has extrapolated the DEX-induced LTP suppression observed in animal studies to clinical situations. We postulated that an *in vivo* study would provide a more clinically relevant experimental rat model of human clinical settings compared to slice preparation.

Therefore, we performed an *in vivo* electrophysiological study in which we investigated the impact of DEX on hippocampal functions, with a focus on the DEX-induced sedative effect. Elucidating the effect of a sedative dose of DEX on the hippocampal LTP in an anesthetized rat may help to characterize the mechanism underlying DEX-induced sedation and/or amnesia in clinical settings.

Materials and methods

General

Adult male Wistar rats (10–12 weeks old), obtained from Shizuoka Laboratory Animal Center in Hamamatsu, Japan, were housed in a room maintained at 22–25°C with a 12-h dark/light cycle and free access to food and water. The rats were handled in accordance with the Guidelines for the Care and Use of Laboratory Animals at Hokkaido University, Graduate School of Medicine. Before the electrophysiological study, each rat was weighed and assigned to a treatment group. DEX was obtained from Hospira Japan Co., Ltd. and was diluted in 0.9% saline and administered intraperitoneally (i.p.) at a volume of 5 mL/kg. The treatment groups were as follows: Group 1, DEX (100 µg/kg, i.p.); Group 2, DEX (30 µg/kg, i.p.); Group 3, DEX (10 µg/kg, i.p.); Group 4, DEX (3 µg/kg, i.p.) and vehicle control (0.9% saline at 5 mL/kg, i.p.).

Electrophysiological recordings

Electrophysiological recordings were obtained as described previously [9]. The rats were anesthetized with 1.2% isoflurane in a mixture of 21% O₂ and 79% nitrogen through a tracheal catheter. Rats were immobilized with 1.2% isoflurane. We previously reported that isoflurane did not affect population spike amplitude (PSA) at doses up to 1.0 minimum alveolar concentration (MAC; approximately 1.4% for adult rats) [10]. In our preliminary study, hippocampal LTP was well established under 1.2% isoflurane (data not shown), leading us to suppose that 1.2% of isoflurane was sufficient to induce anesthesia in this electrophysiological study. Rats were placed in a stereotaxic apparatus with the bregma and lambda in the same horizontal plane, and body temperatures were maintained at $37 \pm 0.5^{\circ}\text{C}$ throughout the recording period. The

concentration of isoflurane and expired CO₂ tension were monitored continuously through a tracheal catheter using an anesthetic gas monitor (5250RGM, Detex-Ohmeda GE Healthcare), and expired CO₂ tension was maintained between 35 and 45 mmHg. A monopolar recording electrode was inserted into the pyramidal cell body layer of hippocampal region CA1 (5.0 mm posterior, 3.0 mm lateral to the bregma; approximately 2.3 mm ventral to the dura), to record the extracellular PSA. A bipolar stimulating electrode was inserted into the ipsilateral Schaffer collaterals (3.0 mm posterior, 1.5 mm lateral to the bregma; 2.8 mm ventral to the dura) to deliver the cathodal stimulus currents (frequency 0.1 Hz, pulse duration 250 μ s). A single electrical stimulation evoked action potentials in the Schaffer collaterals, resulting in activation of pyramidal cells in the CA1 region, and extracellular PSA was recorded (MacLab and PowerLab, ADInstruments Sydney, Australia). The maximal vertical distance from the tangent to the spike trace was recorded as PSA (Fig. 1). To adjust the test stimulation, changes in PSA caused by varied stimulus intensities were recorded; the intensity of the test stimulation was fixed to produce a half-maximal response for each rat. After establishing a stable baseline for 20 min, each dose of DEX or saline was administered intraperitoneally. Twenty minutes after drug administration, LTP was induced by applying high-frequency stimulation (HFS; 10 trains at 1 Hz each, composed of 8 pulses at 400 Hz) at the same intensity as the test stimulus. Then the mean for five PSA measurements before and after the HFS were plotted every 5 min for 60 min after HFS.

Acute sedative effects in rats

We investigated the sedative dose of DEX on Wistar strain rats. Because DEX-induced sedation is easily reversed by physical stimuli [11], we determined the depth of sedation in the rats by using the loss of spontaneous movement as an endpoint, according to our previous study [12]. The loss of spontaneous movement was recorded

for 90 min after administration of each dose of DEX. These results are expressed as a percentage of animals that presented a given behavioral sign.

Statistical analysis

All experimental values are presented as the mean $\pm$ standard error of the mean (SEM). Electrophysiological measurements are expressed as a percentage of the PSA value measured just before HFS, then analyzed with an area under the curve (AUC) of 10–60 min after HFS, using one-way ANOVA with Bonferroni's multiple comparisons test. Probability values (*P*) of <5% were considered to be significant. Statistical analyses were performed using GRAPHPAD PRISM software version 5.0 (Graphpad Software, Inc., San Diego, CA, USA).

Results

Intraperitoneal administration of higher doses of DEX (30 and 100 $\mu\text{g/kg}$) to rats induced a range of sedative effects. These effects included rapid sedation that persisted for over 90 min after drug administration, as indicated by loss of spontaneous movement (Table 1). Electrophysiological testing revealed that HFS of the Schaffer collaterals induced long-lasting increases in PSA in the CA1 field, i.e., LTP induction, in the vehicle group. The maximum response recorded was $182.6 \pm 10.4\%$ ($n = 7$; Fig. 2a). The AUC was significantly decreased in the 100 and 30 $\mu\text{g/kg}$ groups as compared to vehicle rats from 10–60 min after HFS (Bonferroni's multiple comparison test, $P < 0.05$; Fig. 2b). This finding suggests that DEX suppresses the induction of LTP (vehicle: 8.81 ± 0.49 , $n = 7$; DEX 100 $\mu\text{g/kg}$: 5.10 ± 0.43 , $n = 5$ [$P < 0.01$ vs. vehicle]; DEX 30 $\mu\text{g/kg}$: 6.02 ± 0.99 , $n = 6$ [$P < 0.05$ vs. vehicle]; Fig. 2b).

Discussion

In the present study, we demonstrated that a single administration of DEX at a dose of 30 or 100 $\mu\text{g/kg}$ inhibited the induction of LTP in the CA1 region of the adult rat hippocampus. The administration of DEX at concentrations less than 30 $\mu\text{g/kg}$ had no significant influence on LTP induction. Moreover, intraperitoneal administration of DEX at a dose of 30 or 100 $\mu\text{g/kg}$ to rats induced a range of sedative effects. Because the hippocampal LTP was suppressed by these sedative doses of DEX, our findings may signify a causal link between DEX-induced sedative action and hippocampal LTP suppression. To our knowledge, this is the first *in vivo* demonstration that DEX impairs hippocampal LTP in rats.

Our finding is consistent with the report by Takamatsu et al. [8], which showed that DEX impairs LTP induction in mouse hippocampal slices. In contrast, another *in vitro* report found that the same condition did not reduce the induction and maintenance of LTP in the CA1 area of the rat hippocampus [13]. It is unclear whether the discrepancy between these two *in vitro* studies reflects differences in species or experimental protocols, such as the recording systems or LTP induction protocol. In any case, the discrepancy between these two reports should be resolved. Our data may shed some light into the clarification of the effect of DEX on synaptic plasticity in the hippocampus.

We treated rats with a single DEX injection in this study, whereas DEX is commonly used as a continuous infusion with a stable plasma concentration in clinical practice [14]. However, several studies have reported that a single administration of DEX is sufficient to achieve an effective plasma concentration that is stable over time. In an animal study, the reported ED_{50} of the antinociceptive effect of intraperitoneal DEX was $27.6 \pm 5.1 \mu\text{g/kg}$ [15]. Further, the antinociceptive effect of a single administration of DEX was reported to persist for up to 90 min [15]. Plasma drug levels

also remained high for a prolonged duration in adult rats treated with a single dose of DEX (plasma concentration > 1 ng/mL 90 min after one 30 μ g/kg dose of DEX) [16]. Notably, a plasma DEX concentration of 1.09 ng/mL is required for sedation in adult rats [16]. Therefore, even a single DEX administration results in a prolonged elevation of plasma DEX levels and a stable sedative effect. Consistent with these findings, our data showed a prolonged sedative effect of a single administration of DEX (over 90 min) at doses of 30 or 100 μ g/kg; therefore, we presumed that a DEX dose greater than 30 μ g/kg would be sufficient to sedate the rats throughout all electrophysiological measurements, which required more than 80 min.

In this study, we performed an *in vivo* electrophysiological study with anesthetized rats, which may be a more clinically relevant experimental model of human clinical settings compared to slice preparation. Slice preparation is an adequate test system for further investigation into the cellular basis of anesthetic action. However, cutting brain slices disconnects the neurons from the sources of their afferences and from the targets of their efferent projections, eliminating the regulation of neuronal activity by serotonergic projections mainly from the raphe, noradrenaline afferences from the locus coeruleus, acetylcholine innervation from the nucleus basalis, and hormonal modulations [17, 18], all of which are crucially involved in LTP formation. In addition, several studies have demonstrated that GABA is involved in triggering the LTP phenomenon. Consequently, disconnecting a structure from its inputs/outputs can lead to divergent results compared to an intact structure. Therefore, in contrast to a slice preparation study, an *in vivo* electrophysiological study may have clinical implications, providing a realistic picture of the overall functioning of the brain with intact neuronal circuitry. Importantly, our *in vivo* study revealed that sedative doses of DEX impaired the induction of hippocampal LTP. These findings may signify a causal link between DEX-induced sedative action and hippocampal LTP suppression, providing a better understanding of the mechanisms underlying the DEX-induced sedative and/or amnestic

effect.

In conclusion, the findings of the present study showed that the administration of a sedative dose of DEX altered synaptic plasticity in the rat hippocampus. This *in vivo* design may provide novel information regarding the basic actions of DEX in the central nervous system.
