1 • **Summary**

2 **Background:** Although fetuses with Klippel-Trénaunay-Weber syndrome (KTS)
3 show various morphological abnormalities on imaging studies, fetal
4 presentation with hydrops fetalis is relatively uncommon in KTS.

5 **Case:** A 28-year-old Japanese woman who had previously given birth to a
6 healthy infant was referred to us at gestational week (GW) 22 due to huge
7 pleural effusion and ascites. The possibility of fetal pulmonary hypoplasia
8 prompted us to place bilateral thoracoamniotic shunts at GW 23 after
9 extensive discussion with both parents. The bilateral shunts were effective
10 in preventing recurrence of pleural effusion. However, ascites increased
11 gradually and clinical signs of fetal cardiac failure necessitated cesarean
12 section at GW 34. A male infant, weighing 4252 g at birth and 2860 g after
13 removal of ascites, survived to the neonatal period and did not require oxygen
14 since 63 days after birth. The infant left hospital on day 103 with a diagnosis
15 of KTS.

16 **Conclusion:** Fetuses with KTS may present with massive pleural effusion and ascites.
17 Thoracoamniotic shunting may be effective in such hydropic fetuses with KTS.

18 **Key Words:** prenatal diagnosis, pleural effusion, hemangioma, port-wine stain

19 INTRODUCTION

20 Klippel–Trénaunay–Weber syndrome (often simply called Klippel–Trénaunay
21 syndrome, abbreviated to KTS) is a condition that affects the development of blood
22 vessels, soft tissues, and bones. The disorder has three characteristic features: a red
23 birthmark called a port-wine stain, abnormal overgrowth of soft tissues and bones, and
24 vein malformations. Fetal presentation of KTS with massive pleural effusion is
25 relatively uncommon, although fetuses with KTS exhibit a variety of abnormalities
26 detectable on ultrasound and magnetic resonance imaging (MRI) studies, including
27 subcutaneous cystic lesions in the axilla, abdomen, pelvis, and lower limbs, lower limb
28 edema or hypertrophy, and ascites [1,2]. Here, we report a fetus presenting with massive
29 bilateral pleural effusion and massive ascites diagnosed postnatally as having KTS. The
30 parents granted permission for this report.

31

32 PRESENTATION OF THE CASE

33 A 28-year-old Japanese woman was referred to our hospital due to massive pleural
34 effusion, massive ascites, and skin edema in the fetus at gestational week (GW) 22. The
35 majorities of the thorax and abdomen were occupied with pleural effusion and ascites

on MRI study performed at GW22 (Fig. 1). These observations suggested increased risk of pulmonary hypoplasia unless the pleural effusion was removed. Fetal echocardiography detected neither malformed heart nor heart failure. Serological tests and frequent measurement of fetal middle cerebral artery peak systolic flow velocity with Doppler ultrasound suggested that parvovirus B19 infection and fetal anemia were unlikely. Bilateral fetal thoracocentesis on GW23 aspirated 56 mL and 28 mL of fluid suggestive of chyle (abundant lymphocytes in the aspirated fluid) from the right and left lungs, respectively, and the patient was confirmed to have a normal karyotype. However, bilateral massive pleural effusion recurred within 48 h after thoracocentesis. Then, thoracoamniotic shunts were successfully placed bilaterally using two double-basket catheters (shunt tube inner diameter 0.9 mm, outer diameter 1.47 mm; Hakko Co, Nagano, Japan)[3] at GW23 after extensive discussion with the parents. This procedure prevented recurrence of pleural effusion until delivery. However, ascites increased gradually and clinical signs of fetal cardiac failure as evidenced by cardiomegaly (cardiothoracic dimension ratio [CTR] of 45%) and increased skin edema that had once decreased after thoracoamniotic shunting necessitated cesarean section at GW34. A male infant, weighing 4252 g at birth (Fig. 2) and 2860 g after removal of the ascites, survived to the neonatal period and did not require oxygen after postnatal day 63. The

infant left the hospital on postnatal day 103 after control of complicated atrial arrhythmia with a diagnosis of KTS showing all three features of the triad, i.e., port-wine stain in the lower abdomen and left thigh, vascular abnormality as evidenced by pleural effusion and ascites, and left lower limb hypertrophy (below the knee).

DISCUSSION

The main clinical manifestation in this case with KTS was a large amount of fluid accumulated in the thorax and abdomen even at mid-gestation (Fig. 1). Favorable outcome may have been associated with the use of thoracoamniotic shunt in this patient.

Perinatal mortality is high among KTS infants with prenatal presentation involving the fetal thigh; the mortality rate in the neonatal period was 45% among 11 infants after excluding 10 terminated pregnancies [1]. The pleural effusion and ascites were considered to have been due to lymphatic dysplasia in the present case. Lymphatic (vascular) dysplasia accounts for 5.7% of all etiologies of 6361 cases with non-immune hydrops fetalis (NIHF) [4]. NIHF, accounting for ~90% of all cases of hydrops fetalis described to date, should be considered a nonspecific, end-stage status of a wide variety of disorders [4]. NIHF indicates significant fetal compromise and is associated with

high rates of perinatal mortality [5]; among 56 pregnancies with NIHF after excluding 15 terminated pregnancies, 12 (21%) fetuses died in utero and 10 (18%) neonates died within 28 days of life [5]. Thus, an unfavorable outcome was expected in this case of prenatal presentation of KTS with hydrops fetalis.

However, a recent report suggested a favorable outcome in fetuses with pleural effusion treated by thoracoamniotic shunting using a double-basket catheter [3]; in a multicenter, prospective single-arm clinical study to determine the efficacy of thoracoamniotic shunting for fetal pleural effusion with and without ascites ($n = 17$ and $n = 7$, respectively), overall survival rates were 79% (19/24) and 71% (12/17) in cases with hydrops fetalis [3]. If severe and longstanding, fetal pleural effusion has the effect of a space-occupying lesion that impedes normal lung development, with the risk of pulmonary hypoplasia and neonatal death [6]. Thoracoamniotic shunting may have had a favorable effect on lung development in this patient.

Pleural effusion or ascites may develop in adolescents with known KTS [7,8]. In a review by Peng et al. [1], 2 (9.5%) of 21 cases with prenatal presentation of KTS involving the fetal thigh had pleural effusion. Thus, fetuses with KTS may present with pleural effusion with and without ascites, as seen in the present case. Thoracoamniotic shunting may be effective in such hydropic fetuses with KTS.
