Abstract

In this article, we used microlevel data extracted from the 2006 Japanese General Social Surveys to analyze the relationships between self-assessed social position and socioeconomic factors such as income and poverty. We provided the posterior results of the estimation of the Bayesian multivariate ordered probit model and proposed an inequality measure for self-assessed social position on the basis of the posterior results. We state the inequality measure “regret” and show that the distributions of regret differ for people above and below the poverty line.

Keywords: Markov chain Monte Carlo (MCMC), multivariate ordered probit model, ordinal explanatory variables

1 INTRODUCTION

As the standard of living improved because of the rapid postwar development of the Japanese economy, a middle-class consciousness prevailed in Japan. However, economic inequality and poverty have emerged as social issues, as the Japanese economy has been sluggish and the aging population has increased in the 20 years following the bursting of the bubble economy in the early 1990s. The factors that affect people’s perception of social stratification may also be influenced by the response to these changes in socioeconomic conditions.¹

People’s perception of social stratification is related to their subjective well-being and life satisfaction, and a change therein has a visible effect on economic and public policy. For example, when people perceive that their social stratification lowers relative to others or when the distribution of their perception is biased, their frustration against society and the government increases. Thus, national and local political situations can be sensitive to these people’s subjective frustration, which can lead to social uncertainty in some situations. In light of these problems, the method to investigate how people precisely perceive to which stratification they belong should be developed for adopting careful policies. Thus, analyzing the determinants of a person’s perception of his or her social position, hereafter called “self-assessed social position,” is important, as is the analysis of subjective well-being and life satisfaction.

While there have been many studies on self-assessed social position in sociology, there are few studies on the subject in economics. Therefore, the development of statistical methods for analyzing self-assessed social position is required for economics. This problem will be addressed by the methods used in the studies on subjective well-being, which have been under intense investigation in economics.

Subjective well-being is considered to be directly related to income. However, the seminal work of Easterlin (1974) shows that economic growth and subjective well-being are not always positively correlated; subsequently, many studies on issues pertaining to this relationship have been conducted (Blanchflower and Oswald, 2004; Layard, 2005; Di Tella and MacCulloch, 2006; Stevenson and Wolfers, 2008; Di Tella et al., 2010). Our article addresses this issue by focusing on people’s perception of social position.

Many studies deal with Easterlin’s paradox and the relationship between subjective well-being or life satisfaction and socioeconomic or demographic factors. These studies not only verify Easterlin’s paradox but also address other issues such as the availability of subjective data on topics including subjective well-being and life satisfaction in economic analysis and the econometric analysis of ordinal data.

Using panel survey data in Russia, Ravallion and Lokshin (2001) narrow the broad concept of subjective welfare to economic welfare and analyze the relationship between subjective welfare and income. In addition, using the ordered probit method, they investigate how economic welfare is influenced by not only income but also by individual characteristics such as gender, age, marital status, education, and health. Ravallion and Lokshin (2002) analyze the relationship between subjective and objective economic welfare by using the ratio of

total household income to the poverty line as an indicator of objective economic welfare. They point out that people who perceive themselves as poor are not statistically classified as poor in Russia and that a discrepancy exists between subjective welfare and income class.

Blanchflower and Oswald (2004) define a reported well-being function that can be used to analyze subjective ordinal data. This function relates a person’s self-reported well-being to the person’s true well-being or utility function, which is a function of income and demographic and personal factors. They use an ordered logit model to estimate the function. Di Tella and MacCulloch (2006) estimate subjective well-being in Europe and the United States using an ordered probit model in which the explanatory variables are not only personal characteristics— including personal income position, employment status, gender, education, and marital status—but also macro variables— such as GDP per capita, life expectancy, and unemployment rate.

Although the adaptation of subjective well-being to a change in income has been proposed as an explanation of Easterlin’s paradox, Di Tella et al. (2010) use panel data to estimate the adaptation of happiness not only to income but also to status; in this article, happiness is life satisfaction and status is the relative standing of one’s job. They show that adaptation to income and status differs across sub-groups based on gender, political stance, and employment. Using panel data, Luttmer (2005) analyzes the relationship between a person’s reported well-being and his or her neighbor’s earnings and shows that subjective well-being is affected by the person’s relative position.

Analyzing reported happiness data and availability, Di Tella and MacCulloch (2006) find that comparing the happiness of two persons is problematic because of individual differences in the perception of the amount of happiness obtained from consuming various goods. However, the problems of comparing happiness are substantially reduced when analyzing groups rather than individuals (Di Tella and MacCulloch, 2006, p. 29).

Furthermore, Stutzer and Frey (2010) review recent advances of studies on subjective well-being in economics and directions of development. They indicate that many open issues for positive analysis exist in economics and that new insights from these studies can stimulate and expand the debate on happiness.

Using Japanese survey data, the present article aims to empirically investigate the effect of income and poverty on self-assessed social position and the relationship between self-assessed social position and individual characteristics such as gender, age, and education, as in previous studies. We use microlevel survey data extracted from the 2006 Japanese General Social Surveys (JGSS-2006), a nationwide survey conducted using two-stage stratified random sampling.

In questionnaire surveys concerning subjective outcomes such as self-assessed social position, choices are often arranged ordinarily. The data on such ordinal choices can be statistically analyzed using an ordered probit model. The JGSS-2006 also contains several responses that indicate satisfaction in areas such as family life, as well as self-assessed social position; therefore, we estimate a multivariate ordered probit model for these variables. From the frequentist viewpoint, an ordered probit model can be estimated using the maximum likelihood method. After the seminal work of Albert and Chib (1993), who utilize latent variable representation, a Bayesian analysis using the Markov chain Monte Carlo method is often used. See, for example, Greene (2008, Chapter 23).
Carlo (MCMC) method has gained popularity for estimating the ordered probit model. Although the latent variables are unknown, their full conditional distributions (FCD) follow a truncated normal distribution. This makes the estimation of the ordered probit model very tractable in Bayesian analysis.\footnote{See Albert and Chib (1993).}

Further, we can apply Chen and Dey’s (2000) Bayesian multivariate ordered probit model to two or more questionnaire items. Because the latent variables in the multivariate ordered probit model are correlated, we must consider this correlation while estimating the model. Restrictions must be imposed on the parameters in order to identify them. A sufficient condition for this identification problem is that the covariance matrix of the latent variables is defined as a form of the correlation matrix. However, this hinders the estimation of the model. Chen and Dey (2000) have successfully overcome this difficulty by using a joint reparameterization of the correlation matrix and cutoff points for the ordinal data.\footnote{Jeliazkov et al. (2009) discuss in depth the identification problems of univariate and multivariate ordered probit models.}

The model allows us to include a new concept, “regret,” to measure self-assessed social position. Hasegawa and Ueda (2011) introduce regret to measure subjective well-being and define it as the probability with which a respondent of the survey who selects a choice in a multiple-choice question pertaining to social position does not choose any other option indicative of a better social position. Thus, regret is used to analyze inequality in self-assessed social position, whose data are given in ordinal variables, since individual regret, the average regret of a group of people, and some inequality measures of regret can be computed.\footnote{As Kalmijn and Veenhoven (2005) and Hasegawa and Ueda (2011) point out, differences in people’s happiness are not measurable, and thus often ignored. Therefore, this comparability of a subjective index (social position in our article) is an advantage of using regret.}

This article proceeds as follows. In Section 2, following Chen and Dey (2000), we describe the Bayesian multivariate ordered probit model. Further, we describe a method of estimating the coefficients of ordinal explanatory variables on the basis of the posterior results of the multivariate ordered probit model. Section 3 provides the posterior results of the estimation of this model on self-assessed social position by using microlevel survey data extracted from JGSS-2006. In Section 4, using the values of the latent variables, we define the probability related to an individual’s self-assessed social position and an inequality measure for self-assessed social position. Section 5 provides brief concluding remarks.

2 BAYESIAN MULTIVARIATE ORDERED PROBIT MODEL

2.1 Chen and Dey’s Model

Following Chen and Dey (2000, pp.135–140), this section describes the Bayesian multivariate probit model. Let $y_{ij}$ denote the ordinal discrete response of individual $i$ to question $j$ for $i = 1, \cdots, n$ and $j = 1, \cdots, m$; that is, $y_{ij} = c$ for $c = 1, \cdots, C_j$. Further, let $z_{ij}$ denote the latent variable of individual $i$ to...
question \( j \) such that
\[
y_{ij} = c \quad \text{if} \quad z_{ij} \in (\gamma_{j(c-1)}, \gamma_{jc}], \quad i = 1, \cdots, n; \quad c = 1, \cdots, C_j; \quad j = 1, \cdots, m.
\]
(1)
where \( \gamma_{jc} \) is a cutoff point for the \( j \)th ordinal response. While in Chen and Dey (2000), the number of cutoff points in each equation is the same, (1) allows for a different number of cutoff points. We specify that
\[
-\infty = \gamma_{j0} < \gamma_{j1} = 0 < \gamma_{j2} < \cdots < \gamma_{j(C_j-1)} < \gamma_{jc} = \infty, \quad j = 1, \cdots, m,
\]
(2)
where condition \( \gamma_{j1} = 0 \) is required for establishing the identifiability of the cutoff parameters.\(^6\) Latent variable \( z_{ij} \) is assumed to be determined by linear model
\[
z_{ij} = x_{ij}' \beta_j + u_{ij}, \quad i = 1, \cdots, n; \quad j = 1, \cdots, m,
\]
(3)
where
\[
\beta_j = \begin{pmatrix}
\beta_{j1} \\
\beta_{j2} \\
\vdots \\
\beta_{jkj}
\end{pmatrix}, \quad i = 1, \cdots, n; \quad j = 1, \cdots, m.
\]
Defining \( \beta = (\beta_1', \beta_2', \cdots, \beta_m')' \) and
\[
z_i = \begin{pmatrix}
z_{i1} \\
z_{i2} \\
\vdots \\
z_{im}
\end{pmatrix}, \quad X_i = \begin{pmatrix}
x_{i1}' & 0 \\
x_{i2}' & \ddots \\
0 & \ddots & \ddots \\
x_{im}'
\end{pmatrix} = \text{diag}(x_{i1}', x_{i2}', \cdots, x_{im}'),
\]
\[
u_i = \begin{pmatrix}
u_{i1} \\
u_{i2} \\
\vdots \\
u_{im}
\end{pmatrix}, \quad i = 1, \cdots, n,
\]
the linear model for the latent variables is rewritten as
\[
z_i = X_i \beta + \nu_i, \quad i = 1, \cdots, n.
\]
Now, we assume that \( \nu_i \sim N(0, \Sigma) \); that is,
\[
z_i \sim N(X_i \beta, \Sigma), \quad i = 1, \cdots, n,
\]
(4)
where \( \Sigma \) is an \( m \times m \) positive definite covariance matrix. To ensure the identification of parameters, some restriction must be imposed on \( \Sigma \). Here, following Chen and Dey (2000, p.136), in addition to \( \gamma_{j1} = 0 \), we assume that \( \gamma_{j(C_j-1)} = 1 \).\(^7\) We define \( \gamma_j = (\gamma_{j2}, \cdots, \gamma_{j(C_j-2)})' \) \( (j = 1, \cdots, m) \) and \( \gamma = (\gamma_1', \cdots, \gamma_m')' \).

\(^6\)See, for example, Albert and Chib (1993, p.673), and Johnson and Albert (1999, p.131).
\(^7\)Usually, \( \Sigma \) is assumed to be a correlation matrix for identification. See, for example, Chib and Greenberg (1998, p.348).
To complete the Bayesian model, we introduce the prior distributions of the parameters \( p(\beta, \gamma, \Sigma) \). On the basis of Bayes’ theorem, the joint posterior distribution can be written as

\[
p(\beta, \gamma, \Sigma, z | y) \propto p(\beta, \gamma, \Sigma, z) p(y | \beta, \gamma, \Sigma, z)
\]

\[
= p(\beta, \gamma, \Sigma)p(z | \beta, \gamma, \Sigma)p(y | \beta, \gamma, \Sigma, z)
\]

\[
= p(\beta, \gamma, \Sigma) \prod_{i=1}^{n} p(z_i | \beta, \gamma, \Sigma)p(y_i | \beta, \gamma, \Sigma, z_i).
\]

Further, defining

\[
G_{ij} = \{\gamma_{jc}^{(i-1)}, \gamma_{jc}^{(i)}\} \quad \text{if} \quad y_{ij} = c, \ c \in \{1, \cdots, C_j\}, \ j = 1, \cdots, m
\]

\[
G_i = G_{i1} \times \cdots \times G_{im}, \ i = 1, \cdots, n,
\]

we have

\[
p(y_i | \beta, \gamma, \Sigma, z_i) = 1_{(z_i \in G_i)}, \ i = 1, \cdots, n,
\]

where \( 1_{(\cdot)} \) is an indicator function. Now, we specify the prior distributions as follows:

\[
p(\beta, \gamma, \Sigma) = p(\beta)p(\gamma)p(\Sigma) = \left\{ \prod_{j=1}^{m} p(\beta_j)p(\gamma_j) \right\} p(\Sigma),
\]

where

\[
\beta_j \sim N(\beta_{j0}, B_{j0}), \ j = 1, \cdots, m, \ \Sigma^{-1} \sim W(\kappa_0, Q_0^{-1}),
\]

and \( W(\kappa_0, Q_0^{-1}) \) denotes a Wishart distribution with degrees of freedom \( \kappa_0 \) and scale matrix \( Q_0^{-1} \). Further, we introduce the prior distribution of \( \gamma_j \), \( p(\gamma_j) = p(\delta_j | \gamma_j) \), based on the following transformation for the cutoff points (Chen and Dey, 2000, p.140):

\[
\delta_{jc} = \log \left( \frac{\gamma_{jc} - \gamma_{jc}^{(c-1)}}{1 - \gamma_{jc}} \right), \ c = 2, \cdots, C_j - 2
\]

where \( \delta_j = (\delta_{j2}, \cdots, \delta_{j(C_j-2)})' \ (j = 1, \cdots, m) \). We specify \( p(\delta_j | \gamma_j) \) as follows:

\[
\delta_j | \gamma_j \sim N(\delta_{j0}, D_{j0}), \ j = 1, \cdots, m.
\]

Thus, the joint posterior distribution can be written as

\[
p(\beta, \gamma, \Sigma, z | y) \propto p(\beta, \gamma, \Sigma)
\]

\[
\times \left\{ \prod_{i=1}^{n} 1_{(z_i \in G_i)} |\Sigma|^{-\frac{1}{2}} \exp \left[ -\frac{1}{2} (z_i - X_i \beta)' \Sigma^{-1} (z_i - X_i \beta) \right] \right\}.
\]

(5)

Using the MCMC sampling scheme, we can sample parameters \((\beta, \gamma, \Sigma, z)\) from the joint posterior distribution (5). Appendix A provides details on the sampling algorithms.

\[^8\text{See Chib and Greenberg (1998, p.349).}\]
2.2 Relationship between One Ordinal Variable and Other Ordinal Variables

We can use the multivariate ordered probit model (4) to investigate the relationship between one ordinal variable $y_1$ and the others ($y_2, \cdots, y_m$). Dropping the suffix $i$ in (4), we consider population regression $z \sim N(X\beta, \Sigma)$, where $X = \text{diag}(x_1', \cdots, x_m')$, and divide $z$ as $z = (z_1, z_{(-1)})'$. Suppose that $z_1$ is a latent variable associated with a dependent variable of interest $y_1$ and that $z_{(-1)}$ is a vector of latent variables corresponding to the other variables ($y_2, \cdots, y_m$).

Multivariate normal model $z \sim N(X\beta, \Sigma)$ can be used to predict $z_1$ given $z_{(-1)}$. Then, we have

$$p(z|X, \cdots) = p(z_1, z_{(-1)}|X, \cdots) = p(z_1|z_{(-1)}, X, \cdots) p(z_{(-1)}|X, \cdots),$$

where “$\cdots$” denotes the conditioning of the other unspecified variables in the equation. On the basis of the property of the multivariate normal distribution, we obtain

$$z_1|z_{(-1)}, X, \cdots \sim N(\tilde{\mu}_1, \tilde{\sigma}_{11}),$$

(6)

where

$$\tilde{\mu}_1 = x_1'\beta_1 + \sigma_{(-1)}'\Sigma_{(-1)}^{-1}(z_{(-1)} - X_{(-1)}\beta_{(-1)})$$

(7)

$$\tilde{\sigma}_{11} = \sigma_{11} - \sigma_{(-1)}'\Sigma_{(-1)}^{-1}\sigma_{(-1)}$$

(8)

$$X = \begin{pmatrix} x_1' & 0' \\ O & X_{(-1)} \end{pmatrix}, \quad \beta = \begin{pmatrix} \beta_1 \\ \beta_{(-1)} \end{pmatrix}, \quad \Sigma = \begin{pmatrix} \sigma_{11} & \sigma_{(-1)}' \\ \sigma_{(-1)} & \Sigma_{(-1)} \end{pmatrix}.$$
number of valid respondents was 4,254. In the poverty rates announced by the Ministry of Health, Labour and Welfare (MHLW), for example, the poverty rate of households with an adult and a child/children is far higher than the overall poverty rate. Thus, for our analysis, we limited the households to those including two or more adults. A total of 2,220 unit records were obtained after eliminating those that contained missing observations for the variables.

(Place Table 1 here.)

Table 1 presents the definitions of the variables used in the analysis.\textsuperscript{11} The poverty line for equivalent income set by MHLW is based on disposable income; however, it is not applicable here because income in the JGSS data includes tax and social insurance premiums.\textsuperscript{12} Therefore, a poverty line comparable to the income in the JGSS data must be calculated. According to Tanaka (2010), the burden ratio of tax and social insurance premiums in aggregate income is 0.155 for 2007. Assuming that the ratio does not vary significantly from 2006 to 2007, the ratio of aggregate income to disposable income is $1/(1 + 0.155)$. The nominal poverty line based on the disposable income in 2006 is 1,270 thousand yen, as announced by MHLM. Thus, the poverty line comparable to the income in the JGSS data is $1,270/(1 + 0.155) = 1,503$ thousand yen.

(Place Tables 2(a), 2(b), 2(c), and 2(d) here.)

Tables 2 (a) to (d) present the summary statistics of the variables used in the analysis. Table 2 (a) shows the frequencies and percentages of the choices corresponding to the self-assessed social position ($\text{SocPos10}$), which includes seven ordinal choices from “less than or equal to 2” to “greater than or equal to 8.”\textsuperscript{13} Table 2 (b) shows satisfaction with family life ($\text{SatFam}$), with the household budget situation ($\text{SatBudget}$), and with health condition ($\text{SatHealth}$). These variables include five ordinal choices (from 1 to 5). Tables 2 (c) and (d) present the summary statistics of the explanatory variables. Statistics such as the mean and standard deviation of household income in Table 2 (d) are calculated from the numerical values explained in footnote 11.

\textsuperscript{11}Variable $\text{log(income)}$ is the logarithm of annual household income in ten thousand yen divided by the square root of the number of family members. In the case of zero income, we set $\text{log(income)}$ equal to zero. The only income data provided in JGSS-2006 are those for the household income band. The number of income bands are 19, and they are 0 yen, less than 0.7 million yen, 0.7–1 million yen, ..., 18.5–23 million yen, and more than 23 million yen. Following Layard et al. (2008), we construct the numerical values of income on the basis of the income band. Layard et al. (2008, p.1850) construct the income data as follows: “In the cross-section surveys, only income bands are available and these we converted into numerical values using the mid point of each band. For respondents in the lowest income band, we assumed an income of two thirds of the upper limit of the band, and for respondents in the highest income band we assumed an income 1.5 times the lower income limit of the band.”

\textsuperscript{12}The poverty line announced by MHLW is available at the following URL of the Comprehensive Survey of Living Conditions: http://www.mhlw.go.jp/toukei/saikin/hw/k-tyosa/k-tyosa10/2-7.html.

\textsuperscript{13}See the definition of $\text{SocPos10}$ in Table 1.
3.2 Posterior Results of Estimated Equations

The estimated equations are as follows:

\[
\begin{align*}
    z_{ij} &= \beta_{j1} + \beta_{j2} \text{DPov}_i + \beta_{j3} \text{Male}_i + \beta_{j4} \log \left( \frac{\text{Income}_i}{\text{PovLine}_i} \right) \\
    &\quad + \beta_{j5} \text{DPov}_i \times \left[ \log \left( \frac{\text{Income}_i}{\text{PovLine}_i} \right) - \log \left( \frac{\text{Income}_{i-1}}{\text{PovLine}_{i-1}} \right) \right] \\
    &\quad + \beta_{j6} \text{Age}_i + \beta_{j7} \text{Educ}_i + u_{ij}, \quad j = 1, \ldots, 4; \quad i = 1, \ldots, n, \\
\end{align*}
\]

where \( j = 1 \) corresponds to \text{SocPos10} and \( j = 2, 3, \) and 4 correspond to \text{SatFam}, \text{SatBudget}, and \text{SatHealth}, respectively. In the interaction term, \( \log \left( \frac{\text{Income}_i}{\text{PovLine}_i} \right) \) is the average value of \( \log \left( \frac{\text{Income}_{i-1}}{\text{PovLine}_{i-1}} \right) \), and the former is subtracted from the latter. The coefficient of that term is estimated at the average value of \( \log \left( \frac{\text{Income}_i}{\text{PovLine}_i} \right) \) according to Wooldridge (2008, pp. 241–242).

The MCMC simulation was run for 30,000 iterations, and the first 10,000 samples were discarded as the burn-in period. The posterior results obtained thereafter were generated using Ox version 6.3 (Doornik, 2009). We set the prior distributions as follows:

\[
\begin{align*}
    \beta_j &\sim N(0, 100I_7) \\
    \delta_1(\gamma_1) &\sim N(0, 100I_4), \quad \delta_j(\gamma_j) \sim N(0, 100I_2), \quad j = 2, \ldots, 4 \\
    \Sigma^{-1} &\sim W(8, 50I_4). \\
\end{align*}
\]

Tables 3 and 4 present the posterior results of the estimation of (9). Table 5 provides the posterior results of the model with ordinal explanatory variables using equation (6). In these tables, “Mean,” “SD,” and “Median” denote the posterior mean, posterior standard deviation, and posterior median, respectively. Further, “P-value” denotes the \( p \)-value for the convergence diagnostic statistic (CD) proposed by Geweke (1992).

From Table 3, we can infer the following:

- Income positively affects self-assessed social position (\text{SocPos10}) because the posterior mean of the coefficient of the logarithm of the income-deflated poverty line (\( \beta_{14} \)) is positive. However, the posterior means of the coefficient of the poverty dummy (\( \beta_{12} \)) and the coefficient of the interaction of the poverty dummy and the logarithm of the income-deflated poverty line (\( \beta_{15} \)) are negative. Therefore, poverty negatively affects \text{SocPos10}.

\[\text{In Layard et al. (2008, p.1853), the model includes estimations for not only log(Income)}\]

but also \( \log(\text{Income})^2 \). However, the correlation coefficient between those two variables is high, which makes the interpretation of their coefficients difficult. Thus, the model that includes only \( \log(\text{income/PovLine}) \) is estimated in this article.

\[\text{The robustness of the results in Tables 3 and 5 is also checked by estimating the coefficients of (9) for different values of the poverty line (PL) in the supplementary material (Tables B.1 and B.2).}\]
The gender dummy (Male) positively affects SatFam because the sign of the posterior mean of $\beta_{23}$ is positive. However, Male does not notably affect SocPos10, SatBudget, and SatHealth since the 95% credible intervals (CIs) of $\beta_{13}$, $\beta_{33}$, and $\beta_{43}$ include zero.

Age positively affects SocPos10 and SatBudget because the signs of the posterior means of $\beta_{16}$ and $\beta_{36}$ are positive. However, Age does not notably affect SatFam and SatHealth because the 95% CIs of $\beta_{26}$ and $\beta_{46}$ include zero. However, Age negatively affects SatHealth with a 90% CI.

Educational level (Educ) positively affects SocPos10 because the sign of the posterior mean of $\beta_{17}$ is positive. However, Educ does not notably affect the three kinds of satisfaction because the 95% CIs of $\beta_{27}$, $\beta_{37}$, and $\beta_{47}$ include zero.

Furthermore, Table 4 shows that the 95% CIs do not include zero for all elements of $\Sigma$.

(Place Table 4 here.)

Table 5 provides the posterior results of the model with ordinal explanatory variables. From this table, we can infer the following:

- SatBudget positively affects SocPos10, while SatFam and SatHealth do not notably affect it.
- Poverty negatively affects SocPos10, but income and educational level positively affect it.

(Place Table 5 here.)

4 INEQUALITY OF SELF-ASSESSED SOCIAL POSITION

4.1 Probability Associated with Self-Assessed Social Position

In this section, we consider the inequality of self-assessed social position. An advantage of Bayesian analysis is that the value of latent variable $z_{1i}$ can be directly obtained from the posterior results. However, the value of $z_{1i}$ may change with the identification restrictions on the parameters. Therefore, instead of latent variable $z_{1i}$, we consider the probability related to individual $i$’s self-assessed social position, which is defined as

$$ p_i = \Phi \left( \frac{z_{1i} - \bar{z}_{1i}}{\sqrt{\hat{\sigma}_{11}}} \right), \quad i = 1, \ldots, n, \quad (10) $$
where $\Phi(\cdot)$ is the distribution function of the standard normal distribution. $\tilde{\mu}_1$ and $\tilde{\sigma}_{11}$ are defined in (7) and (8), respectively. Using the probability related to self-assessed social position, we can calculate the inequality indices for self-assessed social position.

(Place Figure 1 here.)

Figure 1 contains two boxplots for each $y_1 = c$ ($c = 1, \cdots, 7$); the left one shows the distributions of $p = (p_1, \cdots, p_n)'$ of the respondents whose income is above the poverty line and the right one shows the same for the respondents whose income is below the poverty line. A comparison of these boxplots shows that the medians of the right boxplots are higher than those of the left for each $y_1 = c$, ($c = 1, \cdots, 7$). One explanation for this finding may be that respondents above and below the poverty line differ in their perceptions of social position. The respondents below the poverty line are likely to perceive their social positions as higher because they may be satisfied with something other than income. The respondents above the poverty line, however, do not perceive their social position as higher than those who are below the poverty line because income may be an important factor for their satisfaction. Table 6 shows the number of respondents choosing $y_1 = 1, \cdots, 7$.

(Place Table 6 here.)

### 4.2 Regret over Self-Assessed Position

In this section, we use the inequality measure for self-assessed social position proposed by Hasegawa and Ueda (2011).\footnote{Using the World Values Survey data, Hasegawa and Ueda (2011) propose the regret function for subjective well-being and provide posterior analyses on the inequality of subjective well-being.} We calculate probability $r(z_{i1}|\gamma_{1c}, y_i)$, which denotes the difference between cutoff points $\gamma_{1c}$ and $z_{i1}$:

$$r(z_{i1}|\gamma_{1c}, y_i) = \Pr(z_{i1} < z < \gamma_{1c}|y_i)$$

$$= \Pr \left( \frac{z_{i1} - \tilde{\mu}_1}{\sqrt{\tilde{\sigma}_{11}}} < \frac{z - \tilde{\mu}_1}{\sqrt{\tilde{\sigma}_{11}}} < \frac{\gamma_{1c} - \tilde{\mu}_1}{\sqrt{\tilde{\sigma}_{11}}} \bigg| y_i \right)$$

$$= \begin{cases} 
\Phi \left( \frac{\gamma_{1c} - \tilde{\mu}_1}{\sqrt{\tilde{\sigma}_{11}}} \right) - \Phi \left( \frac{z_{i1} - \tilde{\mu}_1}{\sqrt{\tilde{\sigma}_{11}}} \right) & \text{if } z_{i1} < \gamma_{1c} \\
0 & \text{if } z_{i1} \geq \gamma_{1c} 
\end{cases} \quad (11)$$

We call $r(z_{i1}|\gamma_{1c}, y_i)$ the regretted self-assessed social position of individual $i$ in category $c$.\footnote{If a loss function is defined as $L(z_{i1}, \gamma_{1c}) = 1_{(z \in (z_{i1}, \gamma_{1c}))}$, the posterior risk function can be written as $r(z_{i1}|\gamma_{1c}, y_i) = \mathbb{E}[L(z_{i1}, \gamma_{1c}) | \cdots] = \int 1_{(z \in (z_{i1}, \gamma_{1c}))} \pi(z | \cdots) dz$.}

Further, on the basis of the definition of regretted self-assessed
social position, we have \( r(z_{i1} | \gamma_{1c}, y_i) = 1 - p_i \). When latent variable \( z_{i1} \), which represents an evaluation of person \( i \)'s social position, is greater than cutoff point \( \gamma_{1c} \), from (1), he/she is supposed to perceive himself or herself to be in social position \( c \). Thus, regret denotes the probability that person \( i \) does not choose a higher social position \( c \) as his or her social position. It can also be regarded as the value representing the degree of disappointment that the person has upon failing to attain a higher social position. As regret denotes probability and computation of aggregation and comparison is possible, an inequality of self-assessed social position can be measured by investigating its distribution. Therefore, regret is a useful method for economic and social analysis using survey data.

(Place Table 7 here.)

Table 7 provides the posterior results of regretted self-assessed social position. \textit{regret1} to \textit{regret7} denote the regretted self-assessed social position for categories \( c = 1 \) to \( c = 7 \), respectively. “Mean,” “SD,” and “Median” denote the sample mean, sample standard deviation, and sample median of individual posterior regretted self-assessed social position, respectively; for \( j \leq c \),

\[
\hat{r}_{cj} = \frac{1}{n_j} \sum_{i \in S_j} r(z_{i1} | \gamma_{1c}, y_i), \quad s_{cj} = \sqrt{\frac{1}{n_j - 1} \sum_{i \in S_j} (r(z_{i1} | \gamma_{1c}, y_i) - \hat{r}_{cj})^2},
\]

\[
\hat{r}_c = \frac{1}{n^*_c} \sum_{i \in S^*_c} r(z_{i1} | \gamma_{1c}, y_i), \quad s^*_c = \sqrt{\frac{1}{n^*_c - 1} \sum_{i \in S^*_c} (r(z_{i1} | \gamma_{1c}, y_i) - \hat{r}_c)^2},
\]

where \( S_j = \{i : y_{i1} = j\} \), \( n_j = \#S_j \) (the number of observations in \( S_j \)) and where \( S^*_c = \{i : y_{i1} \leq c\} \), \( n^*_c = \#S^*_c \) (the number of observations in \( S^*_c \)).

\[18\] For example, for \textit{regret2} in Table 7, the Mean and SD of \( y_{i1} = 1 \) denote

\[
\hat{r}_{21} = \frac{1}{n_1} \sum_{i \in S_1} r(z_{i1} | \gamma_{12}, y_i), \quad s_{21} = \sqrt{\frac{1}{n_1 - 1} \sum_{i \in S_1} (r(z_{i1} | \gamma_{12}, y_i) - \hat{r}_{21})^2},
\]

and the Mean and SD of \( y_{i1} = 2 \) denote

\[
\hat{r}_{22} = \frac{1}{n_2} \sum_{i \in S_2} r(z_{i1} | \gamma_{12}, y_i), \quad s_{22} = \sqrt{\frac{1}{n_2 - 1} \sum_{i \in S_2} (r(z_{i1} | \gamma_{12}, y_i) - \hat{r}_{22})^2},
\]

where \( S_1 = \{i : y_{i1} = 1\} \), \( n_1 = \#S_1 \), \( S_2 = \{i : y_{i1} = 2\} \), and \( n_2 = \#S_2 \). Further, the Mean and SD of \( y_{i1} \leq 2 \) denote

\[
\hat{r}_2 = \frac{1}{n^*_2} \sum_{i \in S^*_2} r(z_{i1} | \gamma_{12}, y_i), \quad s^*_2 = \sqrt{\frac{1}{n^*_2 - 1} \sum_{i \in S^*_2} (r(z_{i1} | \gamma_{12}, y_i) - \hat{r}_2)^2},
\]

where \( S^*_2 = \{i : y_{i1} \leq 2\} \) and \( n^*_2 = \#S^*_2 \).
4.3 Measuring the Inequality of Self-Assessed Social Position

In survey questionnaires such as JGSS, social position is investigated by asking respondents their perceptions of their own social positions. The choices are given in an ordinal scale. Dissatisfaction with their position differs even when respondents choose the same position. Regret can represent such dissatisfaction, and can be used to analyze the inequality of self-assessed social position since it is the probability that people do not choose a higher social position.

Table 8 shows the Gini coefficients of regretted self-social position. They are computed from (11) by using a person’s regret for \( c = 1, \ldots, 7 \). The 95% CI does not include zero. The Gini coefficient decreases as \( c \) of regret increases from \( c = 1 \) to 7. regret1 denotes the degree to which a person whose self-assessed social position is the lowest feels dissatisfied about not attaining a higher social position. Table 6 shows that with regard to regret, 106 samples have positive regret, while far more samples have zero regret. Thus, the inequality of regret in all samples of the posterior results is large, and the value of the Gini coefficient is high, near 1. The Gini coefficient is inversely related to \( c \) because more samples have positive regret and fewer have zero regret. In our results, the Gini coefficient decreases greatly when \( c \) increases from 4 to 5, since, as Table 6 shows, the number of samples of positive regret increases by 855.

Although this analysis uses single-year data, the regret of each year can be computed if cross-sectional data or panel data across years are available. Using these data to compute the Gini coefficient allows us to analyze changes in the inequality of regret; that is, we can compare the degree of dissatisfaction among persons who do not attain a higher social position.

Figure 2 shows the boxplots of regretted self-assessed social position and the details of its distribution. The figure titled as “\( y_1 = 1 \)” denotes the distributions of regret for the respondents belonging to \( S_j \) that fail to reach \( \gamma_{1c} (c = 1, \ldots, 7) \). The figures titled as “\( y_1 \leq j \)” (\( j = 2, \ldots, 7 \)) denote the distributions of regret that respondents belonging to \( S_j^* \) fail to reach \( \gamma_{1c} (c = 1, \ldots, 7) \). The vertical axis represents regret and the horizontal axis represents \( c (c = 1, \ldots, 7) \), which denotes the choices of self-assessed social position. Two boxplots are drawn for each \( c (c = 1, \ldots, 7) \) on the horizontal axis in the figures. The left boxplot shows the distribution of regret for respondents above the poverty line, while the right shows that for respondents below the poverty line.

From Figure 2, we infer the following:

- The interquartile range (IQR) of the boxplots in the figures for respondents below the poverty line is wider than that for respondents above the poverty line when \( y_1 \leq 2, \ldots, y_1 \leq 7 \).
Comparing the boxplots of (A) and (B) at the label $c$ of the horizontal axis in the figure titled as “$y_1 \leq c$ ($c = 1, \cdots, 7)$”, the distributions of the respondents above the poverty line skew to the right except in the cases of $y_1 \leq 2$ and $y_1 \leq 4$. However, the distributions of respondents below the poverty line do not skew when $y_1 \leq 6$ and $y_1 \leq 7$, although their distributions skew to the left when $y_1 \leq 2$, $y_1 \leq 3$, $y_1 \leq 4$, and $y_1 \leq 5$. These findings suggest the following three points. Respondents above the poverty line are satisfied with their social position. Respondents below the poverty line who see themselves at a lower social position are not satisfied with their present situation. Among respondents below the poverty line, persons who see themselves at a higher social position hardly display a biased perception about being satisfied with their present social position.

Similarly, the median of the regretted self-assessed social position of respondents below the poverty line is higher than that of respondents above the poverty line for each $c$ ($c = 1, \cdots, 7$) except in the case of $y_1 \leq 7$.

## 5 Concluding Remarks

In this article, using the microlevel data of JGSS-2006, we analyzed the relationships between self-assessed social position and socioeconomic factors such as income and poverty. We estimated the Bayesian multivariate ordered probit model because ordinal data are used for some explanatory variables that represent people’s satisfaction with their family life, household economic situation, and health. We proposed an inequality measure on self-assessed social position, “regret,” which allows us to investigate the effects of poverty on self-assessed social position through a change in its distribution, as it is derived from the probability that a person cannot choose a higher social position.

The main results of our empirical analysis are as follows.

- Income positively affects self-assessed social position, but poverty negatively affects it (see Table 3).

- Satisfaction with the household budget positively affects self-assessed social position, but satisfaction with family life and health do not notably affect it (see Table 5).

- When the ordinal explanatory variables—satisfaction with family life, with the household budget, and with health—are not controlled, Age positively affects self-assessed social position (see Table 3). However, when they are controlled (see Table 5), Age does not notably affect it.

- The median of the regretted self-assessed social position of respondents below the poverty line is higher than that of respondents above the poverty line in most cases (see Figure 2).

- When the dispersion of regretted self-assessed social position is calculated by the IQR of a boxplot, the dispersion of respondents below the poverty line is greater than that of respondents above the poverty line (see Figure 2).
The distributions of the regretted self-assessed social position of respondents above the poverty line skew to the right at each label on the horizontal axis, \(c = 1, \cdots, 7\), in most cases (see Figure 2). However, the distributions of regretted self-assessed social position have two different shapes among those who are below the poverty line. The distributions of the regret of persons whose self-assessed social position is lower skew to the left, but this phenomenon is not observed for persons whose self-assessed social position is higher. This suggests that persons above the poverty line tend to be satisfied with their self-assessed social position. Furthermore, persons below the poverty line whose self-assessed social position is lower tend to be dissatisfied with their current social position, but persons whose self-assessed social position is higher do not exhibit distinct dissatisfaction.

Interestingly, the distributions of regret differ among those below the poverty line. Further investigation is required to determine the reason for the skewness of the distributions. For example, such people may give up trying to achieve higher social positions, or non-economic factors may decrease their regret. The effects of income and poverty on self-assessed social position may depend on the changes in a variety of socioeconomic circumstances. Our future analysis will be extended across years and will use the multi-year JGSS data.

### A SAMPLING ALGORITHMS

Following Chen and Dey (2000, pp.135–140), this appendix describes the sampling algorithm of Bayesian multivariate probit model.

#### A.1 Sampling of \(\beta\) and \(\Sigma^{-1}\)

For the sake of convenience of expression, we replace the \(j\)th factor of \(z_i, X_i, \beta, \Sigma\) and \(\Sigma^{-1}\) as the first factor, that is,

\[
z_i = \left( \begin{array}{cc} z_{ij} \\ z_{i(-j)} \end{array} \right), \quad X_i = \left( \begin{array}{cc} x_{ij} \\ 0' X_{i(-j)} \end{array} \right), \quad \beta = \begin{pmatrix} \beta_j \\ \beta_{(-j)} \end{pmatrix}
\]

\[
\Sigma = \begin{pmatrix} \Sigma_{jj} & \Sigma_{j(-j)} \\ \Sigma_{(-j)j} & \Sigma_{(-j)} \end{pmatrix}, \quad \Sigma^{-1} = \begin{pmatrix} \Sigma_{jj}^{-1} & \Sigma_{j(-j)}^{(-j)'n} \\ \Sigma_{(-j)j}^{(-j)^{'n}} & \Sigma_{(-j)}^{-1} \end{pmatrix}.
\]

Then, we have the following full conditional distributions (FCDs) of \(\beta_j\) and \(\Sigma^{-1}\).

- The FCD of \(\beta_j\) is
  \[
  \beta_{j|\cdots} \sim N(\tilde{\beta}_j, \tilde{\Sigma}_j), \quad j = 1, \cdots, m,
  \]
  where

  \[
  \tilde{\beta}_j = \left( B_{j0}^{-1} + \sigma_{j}^{(j)} \sum_{i=1}^{n} x_{ij} x_{ij}' \right)^{-1} B_{j0}^{-1} \beta_{j0} + \sigma_{j}^{(j)} \sum_{i=1}^{n} x_{ij} z_{ij} + \sum_{i=1}^{n} x_{ij} \sigma_{ij}^{(-j)^{(j)}} (z_{i(-j)} - X_{i(-j)} \beta_{(-j)}).
  \]
• The FCD of $\Sigma^{-1}$ is

$$\Sigma^{-1} \sim W(\tilde{\kappa}, Q^{-1})$$

where

$$\tilde{\kappa} = \kappa_0 + n, \quad Q = Q_0 + \sum_{i=1}^{n} (z_i - X_i \beta)(z_i - X_i \beta)' .$$

Applying Gibbs sampling to the FCDs of (12) and (13), we can generate $\beta_j$ and $\Sigma^{-1}$.

A.2 Sampling of $z$ and $\gamma$

Let $z_{(j)} = (z_{1j}, z_{2j}, \ldots, z_{nj})'$ denote the vector of the $j$th element $z_{ij}$ from $z_i$ ($i = 1, \ldots, n$). Further, let $z_{(-j)}$ denote the vector obtained by removing $z_{(j)}$ from $z$, and let $z_{i(-j)}$ denote the vector of removing $z_{ij}$ from $z_i$. We generate $\gamma_j$ and $z_{(j)}$ from the joint conditional distribution $p(\gamma_j, z_{(j)} | \beta, \Sigma, z_{(-j)}, y)$ ($j = 1, \ldots, m$). The joint conditional distribution $p(\gamma_j, z_{(j)} | \beta, \Sigma, z_{(-j)}, y)$ can be written as

$$p(\gamma_j, z_{(j)} | \beta, \Sigma, z_{(-j)}, y) = p(\gamma_j | \beta, \Sigma, z_{(-j)}, y)p(z_{(j)} | \gamma_j, \beta, \Sigma, z_{(-j)}, y), \quad j = 1, \ldots, m.$$ 

Similar to the sampling of $\beta_j$, for the sake of convenience of expression, we replace the $j$th factor as the first factor. Since $z_{i| \beta, \Sigma, \gamma} \sim N(X_i \beta, \Sigma)$, from the property of the multivariate normal distribution we have

$$z_{ij} | \gamma_j, \beta, \Sigma, z_{(-j)}, y \sim N(\bar{\mu}_{ij}, \bar{\sigma}_{jj})1(z_{ij} \in [0, y]), \quad i = 1, \ldots, n; \quad j = 1, \ldots, m,$$

where

$$\bar{\mu}_{ij} = x_i' \beta_j + \sigma_{(-j)}^{-1} \Sigma_{(-j)} \left( z_{ij} - X_{i(-j)} \beta_{(-j)} \right)$$

$$\bar{\sigma}_{jj} = \sigma_{jj} - \sigma_{(-j)}^{-1} \Sigma_{(-j)}^{-1} \sigma_{(-j)}.$$ 

The distribution of $z_{ij}$ is a truncated normal distribution. We can utilize the method for sampling truncated normal variables proposed by Damien and Walker (2001).

Since $z_{1j}, z_{2j}, \ldots, z_{nj}$ are independent given $\gamma_j, \beta, \Sigma$, we have

$$p(\gamma_j | \beta, \Sigma, z_{(-j)}, y) \propto p(\delta_{ij}(\gamma_j)) \prod_{i,y_{ij}=2}^{\phi} \left( \frac{\gamma_{j2} - \bar{\mu}_{ij}}{\bar{\sigma}_{jj}} \right) - \Phi \left( -\frac{\bar{\mu}_{ij}}{\bar{\sigma}_{jj}} \right)$$

$$\times \prod_{i,y_{ij}=3}^{\phi} \left( \frac{\gamma_{j3} - \bar{\mu}_{ij}}{\bar{\sigma}_{jj}} \right) - \Phi \left( \frac{\gamma_{j2} - \bar{\mu}_{ij}}{\bar{\sigma}_{jj}} \right)$$

$$\times \cdots \times \prod_{i,y_{ij}=C_j-1}^{\phi} \left( \frac{1 - \bar{\mu}_{ij}}{\bar{\sigma}_{jj}} \right) - \Phi \left( \frac{\gamma_{j(C_j-2)} - \bar{\mu}_{ij}}{\bar{\sigma}_{jj}} \right) .$$
where $\Phi(.)$ is the distribution function of the standard normal distribution. Thus, the conditional distribution of $\delta_j$ is

$$p(\delta_j|\beta, \Sigma, z_{(-j)}, y) \propto p(\gamma_j|\beta, \Sigma, z_{(-j)}, y) \prod_{c=2}^{C_j-2} \frac{(1 - \gamma_j(c-1)) \exp(\delta_{jc})}{(1 + \exp(\delta_{jc}))^2}.$$  

(15)

We use a multivariate $t$ distribution, $Mt(\delta_j|\tilde{\delta}_j, \tilde{\Sigma}_{\delta_j}, \nu)$, as a proposal distribution for generating $\delta_j$, where $\tilde{\delta}_j$ is the mode of (15),

$$\tilde{\Sigma}_{\delta_j} = \left\{ \begin{array}{c} \frac{\partial \log p(\delta_j|\cdots)}{\partial \delta_j, \partial \delta'_j} \\ \delta_j = \tilde{\delta}_j \end{array} \right\}^{-1}$$

and $\nu$ is the degrees of freedom. The M-H algorithm for generating $\delta_j$ is as follows:

1. Let $\delta_j^{(t)}$ denote the value of $\delta_j$ at the $t$th iteration.
2. At the $(t+1)$th iteration, sample $\delta_j^p$ from $Mt(\delta_j|\tilde{\delta}_j, \tilde{\Sigma}_{\delta_j}, \nu)$.
3. The transition probability from $\delta_j^{(t)}$ to $\delta_j^p$ is

$$\alpha = \min \left\{ \frac{p(\delta_j^p|\cdots) Mt(\delta_j^{(t)}|\tilde{\delta}_j, \tilde{\Sigma}_{\delta_j}, \nu)}{p(\delta_j^{(t)}|\cdots) Mt(\delta_j^p|\tilde{\delta}_j, \tilde{\Sigma}_{\delta_j}, \nu)}, 1 \right\}.$$  

4. Generate $u \sim U(0,1)$, the uniform distribution on $(0,1)$, and take

$$\delta_j^{(t+1)} = \begin{cases} \delta_j^p & \text{if } u < \alpha \\ \delta_j^{(t)} & \text{otherwise.} \end{cases}$$

We can obtain $\gamma_j$ from $\delta_j$ by using the equation

$$\gamma_{jc} = \frac{\gamma_j(c-1) + \exp(\delta_{jc})}{1 + \exp(\delta_{jc})}, \ c = 2, \ldots, C_j - 2.$$
