### 3 **S1. Ice sheet model resolution**

4 This document describes a model resolution sensitivity study carried out prior  
5 to the experiments presented in the main text.

6 As part of this study we have tested model horizontal grid resolutions of 40,  
7 20, and 10 km, which encompass a range of model resolutions often used for  
8 continental-scale numerical simulations of the Antarctic Ice Sheet (e.g., de  
9 Boer et al., 2015; Pollard and DeConto, 2012; Pollard et al., 2015). This  
10 sensitivity analysis is motivated by a large number of simulations required  
11 for the comparison study of the four hybrid schemes, and the fact that  
12 forward ice sheet modelling at a resolution of 10 km is computationally  
13 expensive. As a result, we have decided to test a 10-km resolution only for  
14 one hybrid scheme (namely HS-3), merely as a proof-of-concept, and to  
15 confirm the low sensitivity of the model results to changes in the grid size  
16 discussed by Pollard and DeConto (2012) and Pollard et al. (2015).

17 The experimental set-up closely follows that of the main experiments  
18 (Section 4), except for a shorter time span for each relaxation/free-evolution  
19 stage (50,000 model-years per stage here vs. 100,000 model-years per stage  
20 in the main experiments) to allow for the use of a model resolution of 10 km,  
21 over a total time span of 200,000 model-years for each model resolution  
22 tested.

23 As shown in Fig. S1 (top row), the ice sheet thickness distribution resulting  
24 from the use of different model resolutions is very similar at the end of the  
25 simulations, with only minor differences which are mostly confined to the  
26 areas near the ice sheet margins.

27 The calibrated basal sliding coefficients (Fig. S1, middle row) exhibit a  
28 relatively higher sensitivity to a change in model resolution, with  
29 discrepancies mainly caused by larger gradients in the lower model resolution

30 runs. This is particularly visible in the simulation that uses a model resolution  
31 of 40 km, where a single calibrated value of the basal sliding coefficient is  
32 used for a larger ice sheet area. This effect is less pronounced in the 20-km  
33 resolution simulation. However, overall the estimated basal sliding  
34 coefficients are robust over the ice sheet-covered area.

35 Modeled ice surface velocities (Fig. S1, bottom row) showcase a good ability  
36 of the model to reproduce observations (Section 5.2), even at the lowest  
37 model resolution of 40 km tested here. However, it is readily visible that  
38 changes in the grid size do affect the resulting ice velocities close to the ice  
39 sheet margins, where small outlet glaciers are often poorly resolved in  
40 simulations using a 40-km resolution. On the contrary, the modeled ice  
41 velocities in the 20-km resolution run closely follow the flow patterns  
42 produced by the 10-km simulation with only small-scale, isolated  
43 discrepancies.

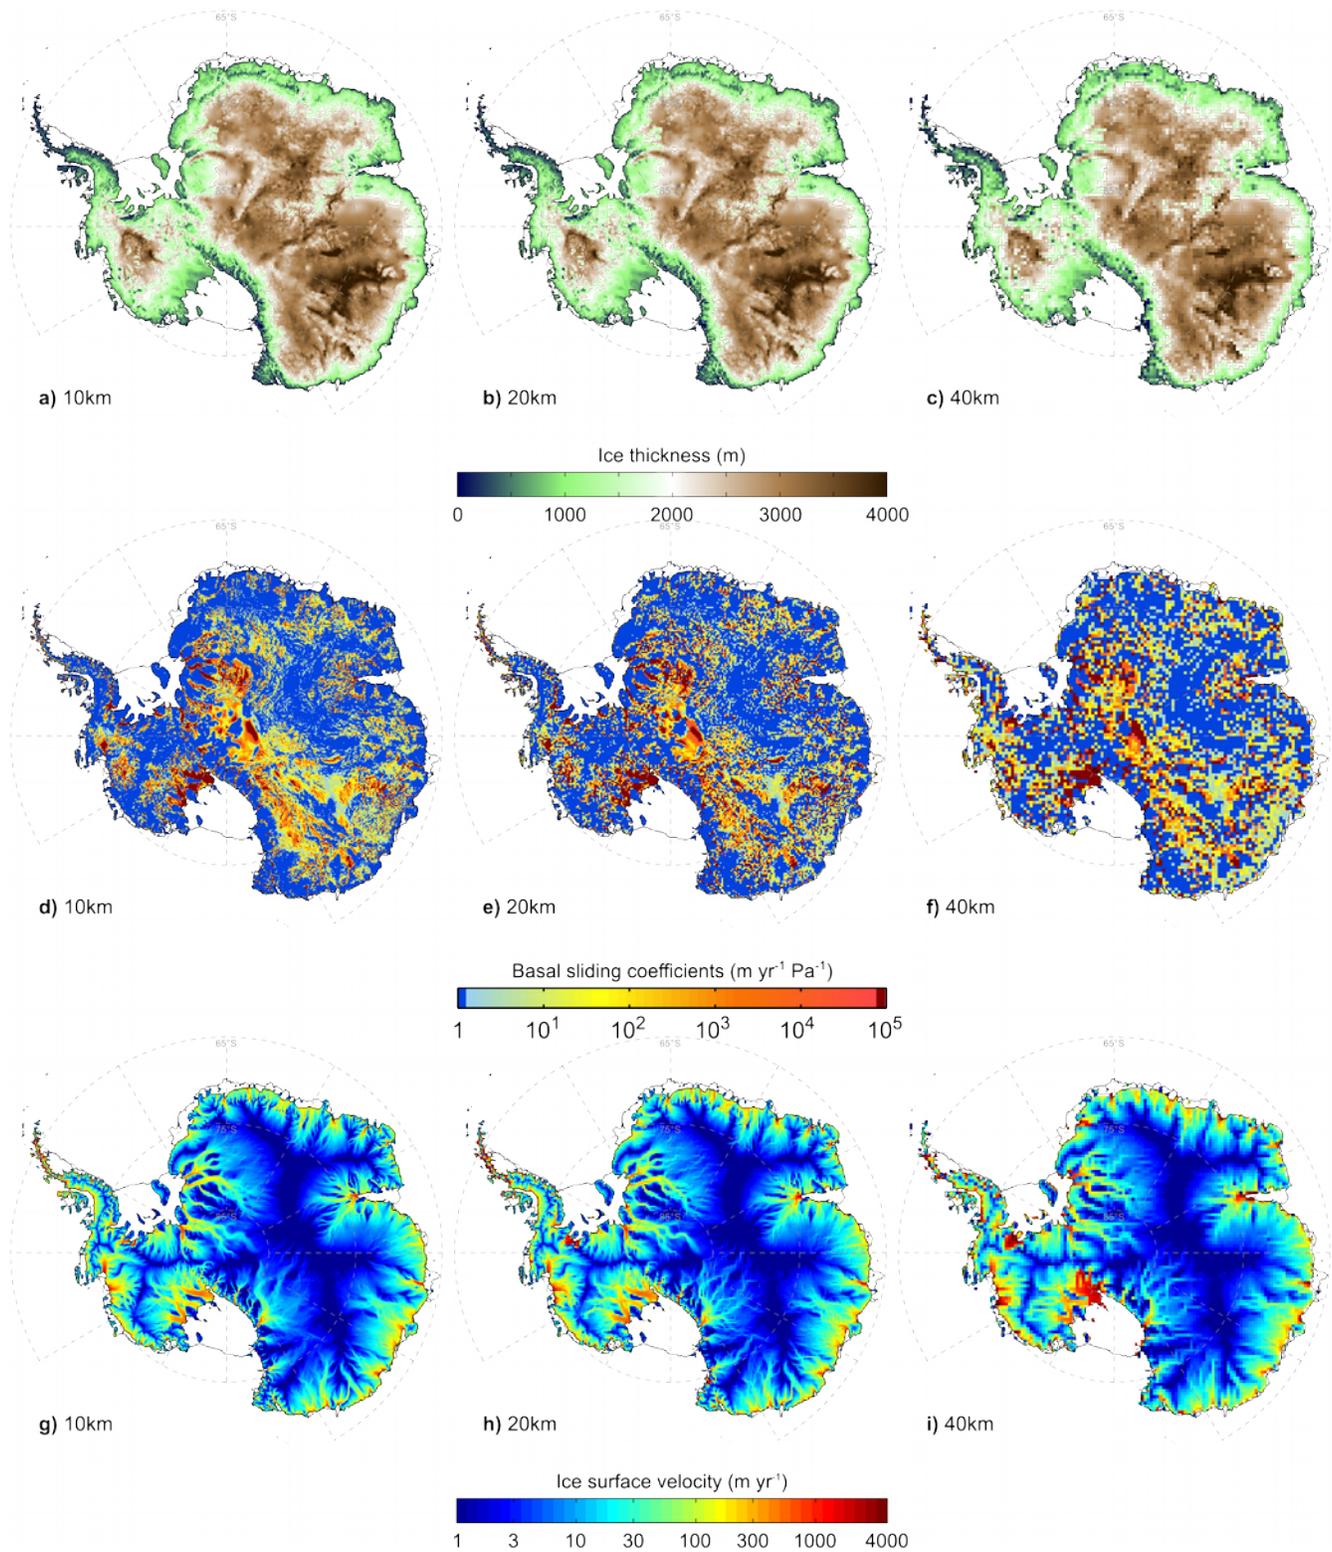

44 Based on a high degree of similarity between our results of the simulations  
45 using model resolutions of 10 and 20 km, we have decided to use the latter  
46 for the comparison of the four hybrid schemes presented in the main text.
