Abstract

Removal of an intron requires precise recognition of the splice donor and acceptor sites located at the 5' and 3' termini of introns. Although the roles of these sequences differ, mutations in both sites easily block normal splicing and produce an aberrant mRNA. For example, many splice-site mutations occur in patients with inherited diseases. Several approaches have been evaluated to restore expression of a functional protein; however, because of the strict requirement for an AG dinucleotide at the 3' terminus of a U2-type intron, no method is available to correct splicing at a mutated sequence. To identify compounds that allow splicing at the non-AG acceptor site, in the present study we constructed a reporter gene with a modified polypyrimidine (Py) tract. However, the modified Py tract mediated splicing at adjacent noncanonical acceptor sites, including the original mutated site. Further, we show that certain flavones such as luteolin and apigenin enhanced aberrant splicing at the noncanonical acceptor site of the reporter gene. These results suggest that the reporter gene and luteolin may be useful for further screening to identify molecules that correct aberrant splicing caused by a disease-associated splice acceptor site mutation.

Introduction

Pre-mRNA splicing must remove introns with high fidelity because incorrect splicing can alter an open reading frame, resulting in the synthesis of an aberrant protein. Most genes contain multiple introns and encode pre-mRNAs that are alternatively spliced. To ensure high fidelity and plasticity, intron definition is an important step, and different strategies are employed for recognition of the splice donor and acceptor sites located at the 5' and 3' termini of an intron, respectively. The donor splice site is determined according to its complementarity with U1 and U6 small nuclear RNAs (1), and the acceptor site is recognized and bound by the heterodimeric U2AF35/U2AF65 complex (2) at the beginning of a splicing reaction.

Introns are classified to be U2- and U12-dependent according to the splice-site sequence and are spliced by the major and the minor spliceosomes, respectively. The canonical U2-dependent acceptor splice site comprises an AG dinucleotide at its 3' terminus and a polypyrimidine (Py) tract precedes the AG sequence. U2AF65 and U2AF35 bind the Py tract and AG dinucleotide, respectively (3-6). The U2AF35/65 heterodimer stabilizes the U2 snRNP bound to the branch point sequence to allow further assembly of the spliceosome. The functions of U2AF65 and U2AF35 partially overlap, and a longer Py tract that results in stronger binding of U2AF65 confers independence from U2AF35 of a splice acceptor site, whereas an intron with a short, low-affinity Py tract requires binding of U2AF35 to the AG dinucleotide (7, 8). Further, the *DEK* proto-oncogene product and hnRNP A1 enhance the fidelity of recognition of the canonical AG by impeding U2AF35 loading at the non-AG site (9, 10), ensuring the rejection of a substrate with a mutated

acceptor site. Approximately 18% of splicing-related mutations found in inherited diseases involve mutations of the AG dinucleotide. (11). These mutations are expected to convert the acceptor site to a noncanonical site, which is skipped in favor of novel cryptic acceptor sites around the original sites (12), resulting in frame-shifts or deletions of mRNA sequences.

In contrast, a recent genome-wide study revealed that noncanonical acceptor sites such as TG dinucleotides are used in particular genes (13), suggesting the presence of a mechanism to bypass the highly accurate selection for the AG dinucleotide. Reduction of hnRNPA1 expression contributes to increased splicing at the noncanonical TG dinucleotide in human $G\alpha_s$ gene (14). If a compound relaxes the fidelity of acceptor site recognition by mimicking the selection mechanism, splicing at the original mutated site would be restored. Because the protein-coding sequence is normal even in the presence of an acceptor site mutation, such a compound may provide a general strategy to cure diseases caused by acceptor site mutations. Drug discovery research that is focused on splicing has identified several novel classes of splicing inhibitors and modulators of alternative splicing (15). However, these compounds induce or inhibit splicing at the canonical acceptor site. To the best of our knowledge, no compound has been analyzed for the ability to restore splicing at the noncanonical acceptor site. Therefore, to discover such molecules, we aimed to develop a reporter that detects changes in splicing efficiency at noncanonical acceptor sites.

Here, we report that modifying the Py tract improves the splicing efficiency at the mutated noncanonical acceptor site. The comparison of a variety of mutations of the AG

dinucleotide revealed that splicing at the noncanonical site is sensitive to the substituted nucleotide. Furthermore, we identified that the flavone, luteolin enhances the use of a noncanonical acceptor site in a reporter gene. This reporter gene and luteolin may help elucidate the mechanism of selection of the noncanonical acceptor site, resulting in the discovery of compounds that relax the fidelity of splicing at pathologically mutated acceptor sites.

Methods and Materials

Plasmids

To construct a model minigene, a genomic DNA fragment of the human fibronectin gene (*FNI*) comprising exons 17–19 (NG_012196.1; 32872–34831) was amplified using the polymerase chain reaction (PCR), and the amplicon was inserted into the pEGFP-C1 vector to fuse the sequence encoding green fluorescent protein (GFP) and that of the *FNI* exon 17. Using the GFP-*FNI* ex17–19 recombinant gene as a template, a fragment including the GFP sequence to introns 18–19 was further amplified using PCR and ligated to the sequence of Emerald Luciferase (Toyobo) present in the modified pcDNA3 vector that contains the I-SceI site upstream of the CMV promoter. To introduce various mutations into the acceptor site, mutated fragments were prepared using PCR, and each fragment was exchanged using HindIII and EcoRI sites. The reporter gene sequences were verified using Sanger sequencing. Sequences of the two introns contain several substitutions and deletions of nucleotides compared with the reference sequence (supplementary file).

Reporter assay

The 293T cell line was cultured in DMEM (Nissui) supplemented with 10% calf serum in an atmosphere containing 5% CO₂. For transfection, cells were plated in 60-mm or 100-mm dishes. The reporter plasmid DNAs were transfected using Jet-PEI according to the manufacturer's protocol. Cells were collected and plated in a multiwell plate 6 h after transfection. Further, compounds were added to the transfected cells 24 h after transfection. After incubation for another 24 h, cells were harvested and lysed in SL buffer (16). Whole-cell extracts were transferred to a black-wall plate to measure GFP fluorescence using Glomax (Promega). After measuring fluorescence, cell extracts were transferred to a white-wall plate and mixed with Steady-Glo (Promega) for detecting luciferase activity using Glomax. After subtraction of average counts of empty wells (background), relative luciferase activity was calculated as a ratio of the luciferase luminescence to GFP fluorescence.

Reverse transcription (RT)-PCR

RNAiso (TaKaRa) and ReverTra Ace RT master mix (Toyobo) were used for RNA extraction and reverse transcription, respectively. ExTaq was used for labeled PCR, and 18–24 PCR cycles were used to adjust for differences in transfection efficiencies. To detect spliced mRNAs, fragments were amplified using the sense primer A (ex17-up: 5'-CAACAAGAAACCACTGGCAC-3') and the antisense primer (pFD-as-IRD1: 5'-GCCCAGCTTCACAGTAGTG-3'-IRD800), and the amplicons were electrophoresed through 2% agarose gel. To detect and quantify labeled PCR products, agarose gels were scanned using an Odyssey imager (Aloka). Applied volumes of PCR products were adjusted for the total intensity of each lane to appear even in the figures. To obtain data

with higher resolution, PCR products generated using the sense primer B (ex2-sense: 5'-CAACAAGAAACCACTGGCAC-3') and pFD-as-IRD1 were electrophoresed on a denaturing polyacrylamide gel using a dNA Sequencer LONG READIR 4200 (Aloka) according to the manufacturer's instruction. After gel electrophoresis, larger original scanned images were cropped using Image analysis (Aloka) and saved as TIFF files to transfer the files to another PC.

Sequencing of PCR amplicons

A GsJr bench-top system (Roche) was used to sequence the RT-PCR amplicons of the spliced mRNAs generated using the reporter gene. For this purpose, fusion primers were designed as per the manufacturer's instructions. Sequences of the fusion primer are divided into four regions: adaptor sequence, key sequence, MID-tag, and annealing region. Adaptor and key sequences were added to purify PCR amplicon using the capture beads and added to indicate the start position of the target gene sequence, respectively. Each MID-tag had a unique sequence and each was added to the sequence data different from samples that were generated by a single sequencing run. To read the target sequence from both direction, sense and antisense fusion primers were designed, and sequences of the annealing region for these primers were 5'-GCC ATC AGT AGA AGG TAG CAG-3' and 5'-CAG TAG TGT CGA AGA ACT CC-3', respectively. RT-PCR was performed using a protocol similar to that described above, except for that 30 cycles were used to detect fragments present in low quantities. Preparation of emPCR, purification of PCR products, and analysis using the GsJr were performed according to the manufacturer's protocol. Obtained data were analyzed using Amplicon Variant Analyzer (Roche) and the cryptic splice sites were manually curated.

Results and Discussion

Modification of the polypyrimidine tract activates several noncanonical acceptor sites near the original site

We attempted to develop a reporter gene that contains the non-AG acceptor site present in an intron predicted to be U2-dependent. For this purpose, we chose intron 18–19 of *FNI*, because this intron is constitutively spliced, and the length of the fragment is suitable for cloning using a plasmid vector (17). The reporter genes contained intron 17–18 and intron 18–19 of *FNI* (Fig. 1A). The splice acceptor site of the second intron (intron 18–19) was mutated, and the first intron (intron 17–18) was unchanged. Because splicing is coupled with other mRNA processing steps, and inhibition of splicing causes defects in other processes (18), we did not mutate the sequence of intron 17–18 of the minigene; therefore, its transcript was always spliced at least once. We modified the Py tract preceding the mutated AG to potentially increase the binding affinity of the mutated transcripts to U2AF65.

If both introns are spliced normally, GFP and luciferase are expressed as a fusion protein, and GFP fluorescence and luciferase luminescence are detected. If a mutation of the AG dinucleotide impedes splicing, intron 18–19 will be retained or a cryptic downstream acceptor site occurring in the luciferase ORF will be used. In either case, GFP-fusion reporter protein will lack the active luciferase domain by a frame-shift or large deletion mutation, resulting in GFP fluorescence alone (Fig. 1B). Thus, the comparison of luciferase luminescence with GFP fluorescence indicates the splicing efficiency at the

mutated acceptor site. We found that the relative luciferase activity of the wild-type reporter pFD-Luc-AG was approximately the same as that of the positive control reporter pFD-Luc-cDNA that did not contain introns, indicating that the reporter construct was normally spliced when there was no mutation (Fig. 2A). In contrast, the pFD-Luc-AT reporter that contained a G to A mutation did not generate detectable luciferase activity; however, the pFD-Luc-Py-AT reporter with the modified Py tract generated a detectable signal, although it was much weaker compared with that of the wild-type reporter.

To confirm that the signal was reflecting altered splicing efficiency, the spliced mRNA was analyzed using RT-PCR. Shorter bands, which represented splicing at the downstream cryptic acceptor site, were generated by mutant reporters (Fig. 2B). The position of the cryptic site is indicated as #8 in the sequence shown in Figure 2D. In addition to the shorter band, a longer band was generated by pFD-Luc-Py-AT that was similar to the size generated by the wild-type reporter. These findings suggest that the increased number of pyrimidine residues in the Py tract allowed splicing at the mutated acceptor site. However, it was unclear if the band corresponded to a transcript spliced at the original site. Therefore, we analyzed RT-PCR products using a sequencing gel that resolved DNA molecules with higher resolution.

Consequently, the larger band detected using pFD-Luc-Py-AT was resolved into seven bands, whereas a single band was detected using the wild-type reporters (Fig. 2C).

Sequence analysis revealed that band #2 was generated by splicing at the original site and that bands #1 and #3–8 were each generated by splicing at seven different adjacent sites, respectively (Fig. 2D). Among these cryptic sites, splicing products labeled #1, #2, and

#4 were in-frame, and these three isoforms were likely responsible for the luciferase activity. This explains the lack of strict correlation between the relative luciferase activities to the ratios of the shorter to longer bands detected in the agarose gels. Because the intron sequence of our reporter does not match that of the consensus sequence of U12-dependent introns, we assume that splicing events detected here at the noncanonical acceptor site were catalyzed by the major spliceosome. The requirement for an extended Py tract that may enhance the binding of transcripts to U2AF65 is consistent with this assumption, although further studies are required to elucidate the mechanism.

Sequence-specific effects on the recognition of noncanonical acceptor sites

To determine if these unusual splicing events were caused by other mutation of the AG dinucleotide, we tested other mutant reporters. The luciferase activities generated by these mutant reporters were generally comparable with that of the original mutant reporter (Fig. 3B and C). In particular, the activities of all-1G mutants were weaker compared with those of the-2A mutants, although there were no large differences among the band intensities in the agarose gels. Further, sequence analysis revealed a significant difference in the splicing efficiency at the original position (Fig. 3D). The-1G > T mutation that we first tested was the only mutation among the-1G mutations that allowed splicing at the original position. Lack of splicing at the AA or AC sites suggests the presence of another fidelity mechanism, which cannot be bypassed by modification of Py-tract in mammalian cells. All-2A mutations allowed splicing at the original position. TG is the most frequently used sequence in the U2-dependent noncanonical acceptor sites in the human genome (13), which may correlate to the higher levels of luciferase activity generated by the TG mutants.

Identification of luteolin as a splicing enhancer at noncanonical acceptor sites

Because our reporter detected splicing at the non-AG acceptor site, we tested the effects on the splicing of 11 compounds used in Chinese traditional medicine. Because the effects of these compounds on cell viability and reporter activity varied, we calculated the difference in induction relative to the luciferase activity generated by the pFD-Luc-cDNA (Fig. 4A) and found that luteolin (marked as #8) increased the relative luciferase activity approximately two-fold, although luteolin increased the basal level of luciferase activity of all reporters through an unknown mechanism.

To assess whether luteolin affected splicing efficiency, we treated cells with luteolin at concentrations ranging from 5 μ M to 50 μ M and analyzed the sizes of the RT-PCR products using agarose gel electrophoresis (Fig. 4B). Luteolin increased the ratio of the larger to the shorter band in a concentration-dependent manner, suggesting that luteolin enhances splicing at the proximal noncanonical acceptor site (Fig. 4C). Because luteolin is a flavone, we tested the flavones apigenin, genistein, and naringenin and found that only apigenin had a similar effect on splicing as that of luteolin (Fig. 4D and E). A recent study has identified hnRNPA2 to be a target of apigenin and shows that apigenin affects alternative splicing (19). Furthermore, the study reported that luteolin, but not naringenin or genistein, binds hnRNPA2; this is notable because the specificity of hnRNPA2 binding is consistent with the present results.

Luteolin does not change the splice-site selection at the noncanonical sites

Because the mutations shown above generated different splicing patterns (Fig. 3C), we tested the effects of luteolin on the splicing of transcripts with other mutations. Luteolin

uniformly increased the levels of the longer isoforms of all mutant reporters, (Fig. 5A and B) and did not generate isoforms that differed from those identified in the absence of luteolin (Fig. 5C). Thus, luteolin may enhance the use of the noncanonical acceptor site by changing the balance of splice-site selection between proximal noncanonical sites (#1–7, Fig. 2D) and distal cryptic AG sites (#8, Fig. 2D). Alternatively, luteolin may decrease rejection rate of a noncanonical acceptor site via relaxing fidelity in AG recognition by U2AF35.

Pre-mRNA processing steps are closely interrelated (20) and that coupling is important for precise recognition of the splice site (21). Because our method combined transient transfection and gene expression driven by the CMV promoter, an excess level of transcripts may uncouple transcription and splicing. The extended Py tract may contribute to restoration of splicing of the mutated reporter transcript in the present model system. Thus, it remains unclear whether a naturally occurring mutation in a U2-dependent intron causes similar use of noncanonical splice sites, whereas the fidelity of acceptor site recognition in U12-dependent introns is lower and activation of adjacent noncanonical acceptor sites occurs in an endogenous gene in a mutated U12-dependent intron (22-24). And also to verify the applicability of our reporter system, it would be interesting to test the effect of luteolin on an endogenous mutated acceptor site. Further investigations to determine the mechanism employed by luteolin to enhance unusual splicing may facilitate the development of strategies to prevent pathologically aberrant splicing by a mutation into the acceptor AG dinucleotide.
