Hokkaido University

Abstract

Premixed diesel combustion is effective for high thermal efficiency and reductions of NO_x and PM emissions, but a reduction of combustion noise is necessary for medium-high load engine operation. The control of the fuel injection has become more accurate because of the technical progress of the common rail fuel injection system, and the target heat release shape, calculated by computation, can be achieved by control of EGR, boosting, fuel injection timing, and injection quantity of multiple fuel injections.

In this paper, the reduction of premixed diesel combustion noise maintaining high thermal efficiency has been investigated by the control of injection timings and heating values of multiple fuel injections. There are two aspects of the combustion noise reduction by multiple fuel injections. One is the reduction of the maximum rate of pressure rise in each combustion cycle, and the other is noise reduction effects by the noise cancelling spike (NCS) combustion.

The research was conducted with both engine simulations and experiments. In combustion noise simulations, the heat release history of multiple injections was approximated by Wiebe functions and the simulated combustion noise was calculated from the fitted curve of the heat release and the coherence transfer function. The structural attenuation (SA) of the test engine was calculated from the power spectrum of the FFT analysis of the in-cylinder pressure wave data and the cross power spectrum of the sound pressure of the engine noise by the coherence method, then the combustion noise (CNL) can be calculated from the structural attenuation and cylinder pressure level (CPL) in the simulation, as shown in equation 4. The simulation results were confirmed by the engine tests.

First, the combustion noise reduction by two stage fuel injection was investigated. The maximum rate of pressure rise changes depending on the combustion occurring separately in the compression and expansion strokes. One heat release was set at TDC and the second before or after the TDC. In the late two stage combustion as shown in Figure 12 (b), the combustion noise reduction was most effectively achieved when the heating value of Q_{2nd} is higher than that of Q_{1st} , however in the early two stage combustion in Figure 12 (a), the Q_{1st} heat release occurs during the compression stroke and the combustion noise reduction by the early two stage NCS combustion is more effective than the combustion noise reduction by the late two stage NCS combustion.

Three stage combustion simulations were also investigated at 0.6MPa IMEP and 2000 rpm. The optimum heat release shape for low combustion noise and high indicated thermal efficiency was

calculated and the role of each part of the heat release in the three stage combustion is discussed. The simulation predicted 87.1 dBA of combustion noise and 50.3 % of indicated thermal efficiency.

Finally, the effects of multiple fuel injections on the degree of constant volume and combustion noise are analyzed and discussed.

Introduction

Much research has been on the reduction of diesel engine combustion noise by engine tests. Kojima reported the relation between combustion noise and burning rates [1] and explained the characteristics of combustion noise generation [2, 3]. Sjöberg [4] and Johansson [5] reported the ringing intensity control and the relation between combustion noise and pressure history was reported by Scarpati [6] and Ghandi [7].

The maximum rate of pressure rise is a main cause of the combustion noise, and Shibata and Shibaike investigated other factors in the combustion noise generation [8]. There, eighteen engine tests were conducted at one maximum rate of pressure rise condition (1.0 MPa/CA), and it was statistically determined that the maximum rate of heat release (RHR_{max}) and the crank angle of 50 % burn (CA_{50}) are the second and third parameters in the combustion noise. The combustion noise reduction was achieved by EGR and boosting to control the RHR_{max} and CA_{50} maintaining the maximum pressure rise rate at 1.0 MPa/CA. Okubo developed a combustion noise simulation method by coherence analysis [9]. This simulation technique was improved for the premixed diesel engine with the Wiebe function [10, 11], making the combustion noise prediction for multiple fuel injections possible.

Fuyuto reported the phenomenon that combustion noise generated in the second combustion could assist in reducing the combustion noise of the first fuel injection, termed “Noise Cancelling Spike Combustion (NCS combustion)” [12]. The NCS effects were investigated by engine tests and simulations, and an optimum heat release shape for low engine noise and high thermal efficiency was suggested [13]. Multiple fuel injection is effective to lower the combustion noise because of the reduction in the maximum rate of pressure rise in each separate combustion and NCS combustion effects.

In this paper, two topics are investigated. One is a further investigation of the combustion noise reduction by the dual fuel injections. Here heat release occurs at TDC and the effects of a heat release before TDC (compression stroke) or after the TDC (expansion stroke) on NCS effects were investigated

The other topic is combustion noise reduction by three fuel injections near TDC. For the dual fuel injections, there is generally amplification of the frequency of the combustion noise and the NCS effect is small. The third fuel injection is effective in lowering of the combustion noise of the amplified frequency and the optimum heat release shape of the three stage combustion was investigated by simulations and engine tests. Finally, the effects of multiple fuel injections on the degree of constant volume and combustion noise are analyzed and discussed.

Experimental

Engine Bench Set up

A schematic outline of the research engine bench is shown in Figure 1. The engine employed in the experiments was a supercharged, single cylinder DI diesel research engine, with a high pressure common rail fuel injection system for injection pressures up to 180 MPa. The specifications of the diesel engine are given in Table 1. The fuel used in the experiments was the commercially available #2 Japanese diesel fuel classified by JIS K2204 specifications (a cetane number of 54). The intake air was measured by an orifice flow meter and mixed with low pressure cooled EGR gas boosted by a supercharger, before being supplied to the engine. The intake manifold was equipped with an electric heater to maintain the intake air temperature at 25 °C. The engine was equipped with a pressure transducer (Kisler 6125A) and pressure data was transmitted to a PC as 45 cycles of crank angle resolved pressure data averaged over the 45 cycles. For all test conditions in this paper, the water and engine oil temperatures were maintained at 80 °C.

Fuel injection system	Common rail
Nozzle hole	$\phi 0.125 \times 7$
Spray angle	156°
Connecting rod/crank radius ratio	L/R=3.1

Noise Measurements and Calculations

Measurements of the Engine Noise

The engine and combustion noise were evaluated with the noise measurement arrangement shown schematically in Figure 2. The supercharger in the right side is surrounded by the acoustic absorption panels and materials, and microphones were set at two sampling positions at the cylinder head top height (one 1 m away from the front of the engine and the other 1 m away to the left of the engine) and engine noise was collected from the left side and front of engines, avoiding the sampling of the transmission noise in the rear side of the engine. The sampled noise was averaged and analyzed by an FFT sound analyzers (Onosokki LA-1410 and DS-3000) and a 1/3 octave band filter was used for the analysis of the frequency characteristics.

Figure 2. Engine noise measurement setup

Calculations of Combustion Noise [9]

The model used to analyze the engine noise is outlined in Figure 3. The engine noise value is comprised of the combustion noise level by the coherence method (CCNL) and the mechanical noise level (MNL) as shown in equation 1 below, assuming that the cylinder pressure and combustion noise levels are closely related. The transfer characteristic H was calculated from the power spectrum by the FFT analysis of the in-cylinder pressure waveform and the cross spectrum of the sound pressure of the engine noise level and pressure waveform. With this, the coherence combustion noise level (CCNL) is calculated from the in-cylinder pressure level and the transfer characteristics H by equation 2.

The pressure changes produce vibrations, transfer, and attenuation in the cylinder block, before it is released from the surface of the engine as combustion noise. The frequency characteristics are specific to the engine used. The engine structure attenuation (SA) can be calculated from the coherence combustion noise level and cylinder pressure level by equation 3, it was calculated under several conditions and averaged to provide a representative structure attenuation curve. Figure 4 shows the frequency characteristics of the structure attenuation (SA), and the combustion noise level (CNL) in the engine tests and simulations are calculated from the cylinder pressure level (CPL) and the structure attenuation (SA) by equation 4. (The direct noise measurements in Figure 2 are only conducted to determine the engine transfer function H. Once the structure attenuation is obtained, the combustion noise is calculated by equation 4.)

Figure 3. Engine noise generation model

Figure 5. Equal loudness curve of a pure sound at 60 phon for the human ear

$$SPL = CCNL + MNL \quad (1)$$

$$CCNL = CPL * H \quad (2)$$

$$SA = CCNL - CPL \quad (3)$$

$$CNL = SA + CPL \quad (4)$$

SPL : Sound pressure level [dBA]

$CCNL$: Combustion noise level by cohent method[dBA]

MNL : Mechanical noise level [dBA]

H : Transfer characteristic

SA : Structure attenuation [dBA]

CNL : Combustion noise level [dBA]

CPL : Cylinder pressure level [dB]

Figure 4. Structural attenuation of the test engine

Figure 5 shows the equal loudness curve of 60 phon pure sound for the human ear. For example, 60 dB of a 1 kHz pure sound (Point 1) is equivalent to 87 dB of 63 Hz (Point 2). This curve shows that the sensitivity of the human ear changes with frequency. Typically the sensitivity of the human ear is low below approximately 600Hz and above 3000 Hz, and is highest in the 1000-3000 Hz range. The sensitivity of the human ear changes depending on the frequency range. Therefore, the “A” weighted sound pressure level, the dBA, was used to evaluate the perceived loudness of the overall combustion noise.

Simulation methods

Wiebe Curve Fitting to Three Stage Combustion

The heat release histories were approximated by the Wiebe function, the simulated combustion noise was then calculated from the fitted curves of the heat release and the coherence transfer function, as a result the effects of the heat release history on the combustion noise and indicated thermal efficiency were investigated. An example of the heat release shape in three stage injection is shown in Figure 6. The heat release history was synthesized by introducing the Wiebe function in equation 5 four times: one time for the low temperature heat release (LTHR) and one each for the first, second, and third high temperature heat releases (HTHR). In each of these heat release calculations, the Wiebe functions were fitted to the heat release history of three stage combustion in the engine test and the parameters M and θ_z in Table 2 were obtained and used in the further simulations.

Figure 6. Approximation by the Wiebe function for the three stage combustion

Table 2. The values of parameters M and θ_z in the Wiebe function for Q_{1st} , Q_{2nd} and Q_{3rd}

	LTHR	Q_{1st}	Q_{2nd}	Q_{3rd}
M	1.5	2.15	2.2	2.1
θ_z	4.7	5.9	5.3	6.5

The in-cylinder pressure history was calculated from the heat release history by the Runge-Kutta numerical method in equation 6, and the kappa is calculated every 0.20 degree of crank angle from the in-cylinder temperature and the cylinder gas composition. The overall

combustion noise and frequency characteristics of the combustion noise were calculated from the frequency characteristics of the in-cylinder pressure by Fourier transformation and the structure attenuation.

$$\frac{dQ}{d\theta} = 6.9 \cdot \frac{Q_{total}}{\theta_z} \cdot (M+1) \cdot \left(\frac{\theta}{\theta_z}\right)^M \cdot \exp\left\{-6.9 \cdot \left(\frac{\theta}{\theta_z}\right)^{M+1}\right\} \quad (5)$$

Q_{total} : Total heat release [J]

θ_z : Combustion duration [°CA]

M : Parameter M [-]

θ : Crank angle [°CA]

$$\frac{dQ}{d\theta} = \frac{\kappa}{\kappa-1} \cdot P \cdot \frac{dV}{d\theta} + \frac{1}{\kappa-1} \cdot V \cdot \frac{dP}{d\theta} \quad (6)$$

Q : Heat release [J]

κ : Ratio of specific heats [-]

P : Pressure [Pa]

V : Volume [m³]

θ : Crank angle [°CA]

To evaluate the accuracy of the simulation data, the combustion data obtained by engine test experiments and simulations were compared. The heat history of the engine data and the approximate history of the heat release by the Wiebe function are plotted together in Figure 7, and the combustion noise data of the experiments and simulation at 100-8000 Hz are plotted in Figure 8. The frequency characteristics of the simulation were very similar to the experiments, and this verifies that the combustion noise could be evaluated by the simulation.

Figure 7. Heat release data in experiment and simulation

Figure 8. Plot of the combustion noise of the experiment and simulation

Figure 9 shows a rate of heat release and rate of pressure rise in two stage combustion and Figure 10 shows an explanation of amplifying and reduction phenomenon of combustion noise. The time difference in the crank angle at the peaks of the pressure rise rates between the first and second fuel injections is defined as $dP/d\theta_{1-2}$ in Figure 9. Equations 7 and 8 show the amplifying and reduction frequencies between Peaks 1 and 2. The Δt in the equations is the duration (sec) of $dP/d\theta_{1-2}$, and Δt equals $(dP/d\theta_{1-2})/12000$ as the engine is operated at 2000 rpm.

$$\text{Amplifying frequency [Hz]: } fn = n_A / \Delta t \quad (7)$$

$$(n_A = 1, 2, 3, \dots)$$

$$\text{Reduction frequency [Hz]: } fn = (2n_c + 1) / 2\Delta t \quad (8)$$

$$(n_c = 0, 1, 2, 3, \dots)$$

Figure 9. Heat release and pressure rise data in two stage combustion

As shown in equation 4, the combustion noise (CNL) is consisted from structure attenuation (SA) and cylinder pressure level (CPL). The SA is specific and constant for the test engine, and the changes in combustion noise is caused by the CPL. Here, the combustion noise in two stage combustion was explained by the CPL in Figure 10, and the frequencies of noise amplification and reduction by the interferences of two stage combustion noises appear in a cyclic manner. If the noise reduction can be done at the loudest frequency range for the engine, the overall combustion noise can be reduced. This is the basic idea of the two stage NCS combustion.

Figure 10. Parameter variables in the simulations

For the three stage combustion in Figure 11, the interferences of combustion noise in Peaks 1-2, Peaks 2-3, and Peaks 1-3 appear, and the combustion noise can be reduced by changing the duration of $dP/d\theta_{1-2}$, $dP/d\theta_{2-3}$, and $dP/d\theta_{1-3}$ and the heating value ratio between Q1, Q2 and Q3. It is investigated in Tests 2-4. This effect is investigated in Tests 2-4.

Figure 11. Parameter variables in the simulations

Method of the Indicated Thermal Efficiency Calculations

The cylinder gas composition at each crank angle is calculated for the simulated heat release history. This allows the pressure, mean temperature, specific heats, specific heat ratios, and generated work to be calculated for the expansion stroke. The cooling loss is calculated by the Hohenberg equation and the cylinder temperature from the IVC to the EVO timings (the Woschni equation was

considered, but the Hohenberg equation was found to agree better with the engine test data here). The exhaust heat loss is calculated from the enthalpy difference between the intake and exhaust gases. The input energy is the total of the integral of the heat release rate and the cooling loss. Altogether this made it possible to calculate the indicated thermal efficiency.

Definition of Parameters in the Simulations

An example of the history of the rates of heat release and pressure rise calculated by simulation is shown in Figure 11. The heat releases by the three injections were defined as the Q_{1st} , Q_{2nd} , and Q_{3rd} . The time differences in the crank angle at the peaks of the pressure rise rates in the first-second heat releases, first-third heat releases, and second-third heat releases were defined as the $dP/d\theta_{1-2}$, $dP/d\theta_{1-3}$, and $dP/d\theta_{2-3}$ respectively.

Test Conditions for Simulations and Engine Tests

All the engine tests and simulations are conducted at 2000 rpm in engine speed.

Test 1: Combustion Noise Reduction by the Two Stage Fuel Injection (Engine Tests)

The effects of the combustion before the TDC, the compression process, and after the TDC, the expansion process, on the degree of constant volume and combustion noise reduction by the NCS (noise cancelling spike) were investigated. Figure 12 (a) is termed early two stage combustion: the crank angle of the peak heat release in the first fuel injection is before the TDC and the crank angle of the peak heat release in the second fuel injection is at the TDC. Figure 12 (b) is named late two stage combustion: the crank angle of the peak heat release in the first fuel injection is at the TDC and the crank angle of the peak heat release in the second fuel injection is after the TDC.

Figure 12. Definitions of (a) the early two stage and (b) late two stage combustions

The test conditions are shown in Table 3. The engine was operated at 2000 rpm, and four types of engine tests were conducted.

(1) Single Heat Release Test

The crank angle of the peak heat release was at the TDC and the IMEP was 0.35 MPa. This is the basic condition of premixed diesel combustion.

(2) Late two stage Combustion (Heat release phases: Figure 12 (b))

The electrical signal was given to the ECU (Engine control unit) of the common rail system to ensure equal heating values in the first and second heat releases, and the timing of the start of the second

injection was retarded from -4.0 to +2 CA ATDC, maintaining an 0.70 MPa of IMEP. The effects of the two stage combustion on the combustion noise and degree of constant volume were investigated.

(3) **Late two stage Combustion (Equal maximum rates of heat release in the first and second combustions)(Heat release phases: Figure 12 (b))**

In the late two stage combustion, the second combustion may become diffusion combustion in the expansion stroke, and the combustion noise reduction by NCS effect is small. To avoid this, the second heat release was increased and the first heat release was reduced a similar amount to maintain the equal maximum rate of heat releases (80 J/CA) for the first and second combustions. The IMEP was maintained at 0.7 MPa and the SOI (start of injection) of the second fuel injection was -4.0 CA ATDC.

(4) **Early two stage Combustion (Heat release phases: Figure 12 (a))**

The maximum rate of heat release in the second fuel injection was maintained at 80 J/CA, and the SOI timing of the first injection was at -19.5 CA ATDC or -18.5 CA ATDC. The fuel quantity of the first injection was varied to maintain 0.7MPa of IMEP.

Table 3. Operational conditions for two stage combustion

Test name	Combustion phase	IMEP	1st Fuel injection		2nd Fuel injection	
			SOI*	Duration*	SOI*	Duration*
		Mpa	CA ATDC	msec	CA ATDC	msec
Test 1-(1)	Single	0.35	-15.50	0.280	-	-
Test 1-(2)	Reat two stage	0.70	-12.25	0.261	-4.00	0.258
			-13.25	0.261	-2.00	0.313
			-13.50	0.261	0.00	0.333
			-13.25	0.261	2.00	0.275
Test1-(3)			-12.75	0.233	-4.00	0.280
Test1-(4)	Front two stage		-19.50	0.218	-8.75	0.330
			-18.50	0.230	-8.00	0.314

* Start of injection (SOI) and injection durations are the input values for EDU

* Start of injection (SOI) and injection durations are the input values for EDU

These test results are arranged by the degree of constant volume and combustion noise rather than by thermal efficiency, because the IMEPs of the single injection and two stage combustions were different.

Test 2: Effects on Combustion Noise of the Three Stage Combustion near the TDC (Simulation)

To investigate the mechanism of multiple fuel injections on the reduction of combustion noise, a three stage combustion near the TDC was attempted by simulation. In Figure 13 the red curve shows the optimum heat release shape for the late two stage combustion calculated by simulation [13], and one more heat release was added ahead of the following two stage combustion. The heating value of the first heat release is a parameter variable varied from 100 J to 500 J, with the $dP/d\theta_{1,2}$ and $dP/d\theta_{2,3}$ maintained 3 CA.

Figure 13. The simulation method in Test 2

The optimization of the triple phase combustion was investigated by the simulation in Test 3 and compared with the actual engine tests in Test 4.

Test 3: Optimization of the Heat Release Shape for Low Combustion Noise and High Thermal Efficiency in Three Stage Combustion (Simulation)

In this simulation, the IMEP was maintained at 0.56 MPa, and the crank angle of the peak heat release in the second fuel injection was set at TDC. In each of the heat releases, the M and θ_z in the Wiebe functions were the same as shown in Table 2. The parameter variables in the simulations were as follows:

- (1) The length of time in crank angle between the peaks of the rate of pressure rise in Peaks 1 and 2 ($dP/d\theta_{1,2}$) was varied from 3 to 5 CA
- (2) The length of time in crank angle between the peaks of the rate of pressure rise in Peaks 2 and 3 ($dP/d\theta_{2,3}$) was varied from 3 to 7 CA
- (3) The heating values for the Q_{1st} , Q_{2nd} , and Q_{3rd}
 - a) The total amount of Q_{1st} , Q_{2nd} , and Q_{3rd} is 585 J.
 - b) The Q_{1st} value was varied from 75 J to 435 J in 40 J steps.
 - c) The Q_{2nd} value was varied from 75 J to 275 J in 40 J steps.
 - d) The Q_{3rd} value was 585 J minus the sum of the Q_{1st} and Q_{2nd} values.
($Q_{3rd}=585 - Q_{1st} - Q_{2nd}$ and $Q_{3rd} \geq 75$ J)

The details of the heat release shape in the three stage combustion are shown in Figure 14.

Figure 14. Parameter variables for the simulations in Test 3

Test 4: Evaluation of Accuracy of the Simulation Results in Test 3 by Engine Tests

The accuracy of the simulation results was evaluated by the engine test. With the test engine, the first and second heat releases show premixed diesel combustion, however the third heat release may become diffusion combustion in the three stage combustion (Appendix 2). To further investigate this, the engine was operated with three types of two stage combustion ($Twin_{1-2}$, $Twin_{2-3}$, and $Twin_{1-3}$) representing the optimum three stage combustion in Test 2, as shown in Figure 15, and the combustion noise reduction of the three stage combustion was determined with the data of the two stage combustions.

Figure 15. Two stage combustions in Test 3 ($Twin_{1-2}$, $Twin_{2-3}$, and $Twin_{1-3}$)

Test 5: Effects of Multistage Combustion on the Indicated Thermal Efficiency and Combustion Noise (Simulation)

The optimum heat release shapes of the single stage, two stage, and three stage HTHR combustions for combustion noise and degree of constant volume were calculated and the multistage combustion effects are discussed.

Results and Discussion

Test 1: Combustion Noise Reduction by the Two Stage Fuel Injections (Engine Tests)

Figure 16 plots the overall combustion noise vs the degree of constant volume for two stage fuel injections in Test 1, and Figure 17 shows the rate of pressure rise in late two stage combustion (Test 1-(2)). When the second fuel injection timing was 2 CA ATDC, the overall combustion noise was 92.7 dBA. With the earlier start timing of the second fuel injection, the degree of constant volume increased, the maximum rate of pressure rise of the second fuel injection increased as in Figure 17, and the combustion noise was reduced 0.7 dBA by the noise cancelling spike (NCS) effect as in Figure 16. When the second injection timing was -4 CA ATDC, the peaks of the maximum rates of pressure rise ($\Delta t = dP/d\theta_{1-2}$) is 3.3 CA. In Table 4, the amplifying and reduction frequencies are listed, and it shows that the combustion noise at 1500-2000 Hz is reduced and the combustion noise at 3000-4000 Hz is amplified, calculated by the equations 7 and 8. Comparing the black and red lines in Figure 19, the combustion noise at 1600 Hz was reduced but increase at 3150 Hz in black line, and it was proved that the combustion noise frequency can be controlled by the peak duration of the maximum rate of pressure rises ($\Delta t = dP/d\theta_{1-2}$).

In Test 1-(3), the peak of the first heat release was reduced to 80 J/CA by the reduction of the first fuel injection quantity and the heating value of the second injection was increased maintaining the IMEP of 0.7 MPa, as shown by the blue curve in Figure 18. The combustion noise was reduced to 89.1 dBA (the red triangle plot in Figure 16), and the combustion noise at 600-3000 Hz was reduced substantially (blue line) as shown in Figure 19, due to the reduction in the maximum rate of pressure rise in the first combustion and the stronger NCS effect.

Figure 20 shows the rates of pressure rise of the early two stage combustion in Test 1-(4). When the start of the first injection was at -18.5 CA, the maximum rates of pressure rise of the first and second injections were similar, and the combustion noise was 87.7 dBA maintaining the degree of constant volume as shown in Figure 16. The frequency characteristics of early two stage combustion in Test 1-(4) is shown in Figure 21. The combustion noise at 3000 Hz in the early two stage combustion (Figure 21) is lower than those of the late two stage combustions in Figure 19. In the early two stage combustion, the first heat release occurs in the compression stroke and the high maximum rate of pressure rise in the first heat release reduces the combustion noise of the second heat release by the NCS effect. In the late two stage combustion, the second combustion occurs in the expansion stroke, the maximum rate of pressure rise in the second combustion is low, and the combustion noise reduction by the NCS effect of late two stage combustion is lower than that of early two stage combustion.

Test 2: Effects on Combustion Noise of the Three Stage Combustion near the TDC (Simulation)

To investigate the mechanism of multiple fuel injections on the reduction of combustion noise, three stage combustion near the TDC was simulated. Here, one heat release was added ahead of the optimum two stage combustion for low engine noise and the heating value of the first heat release was varied from 100 J to 500 J, as shown in Figure 13. Figure 22 plots the overall combustion noise versus the indicated mean effective pressure. The overall combustion noise reduces by the NCS effect. When the first heating value is 200 J, the overall combustion noise is 1.2 dBA lower than that of the two stage combustion (the 0J case), and the overall combustion noise increased with the increase in the first heating value above 200 J.

Figure 22. The overall combustion noise vs IMEP in Test 2

The blue curve in Figure 23 shows the three stage combustion at Point A in Figure 22, the lowest overall combustion noise condition, and the three stage heat release was disassembled into two sets of two stage heat releases, the $Twin_{2-3}$ and $Twin_{1-3}$, to investigate the reduction and amplifying frequencies of combustion noise further.

Figure 23. Three stage combustion at Point A in Figure 22 and two sets of two stage heat releases, $Twin_{2-3}$ and $Twin_{1-3}$

In equation 4, the combustion noise level (CNL) is comprised of the structure attenuation (SA) and the cylinder pressure level (CPL). The SA is specific and constant for the tested engine, and the changes in combustion noise would be caused by the CPL. Figure 24 plots the CPL for the three stage combustion and two sets of two stage combustions ($Twin_{1-3}$ and $Twin_{2-3}$), and the frequency characteristics of the combustion noises by these three combustions are shown in Figure 25. The amplifying frequency and the frequency where $Twin_{1-3}$ is reduced are around 2000 Hz and 1000 Hz respectively, and the frequency of $Twin_{2-3}$ reduction is around 1900 Hz. The amplified frequency of $Twin_{1-3}$ overlaps the frequency where $Twin_{2-3}$ is reduced and the cylinder pressure level of the three stage combustion is reduced around 2000 Hz (blue dotted curve in Figure 24). Figure 25 shows that there is a reduction in combustion noise around 2000 Hz.

Figure 25. Frequency characteristics of three stage combustion and two sets of two stage heat releases, $Twin_{2-3}$ and $Twin_{1-3}$, in Figure 23

Test 3: Optimization of the Heat Release Shape for Low Combustion Noise and High Thermal Efficiency in Three Stage Combustion (Simulation)

The length of time in crank angle between the peaks of the rate of pressure rise in Peaks 1 and 2 ($dP/d\theta_{1-2}$), the length of time in crank angle between the peaks of the rate of pressure rise in Peaks 2 and 3 ($dP/d\theta_{2-3}$), and the heating values Q_{1st} , Q_{2nd} , and Q_{3rd} in Figure 14 were the parameters that were varied in the simulations. An example of the simulation results is shown in Figure 26, here $Q_{2nd}=155$ J and $dP/d\theta_{1-2}=3$ CA, and the $dP/d\theta_{1-2}$ and the heating values of Q_{1st} , Q_{2nd} , and Q_{3rd} were as noted in the figure. The overall combustion noise is the lowest when $Q_{1st}:Q_{2nd}:Q_{3rd}=195J:155J:235J$. The reason why these optimum heating values result in the lowest combustion noise is that the third combustion occurs in the expansion stroke, and as Q_{3rd} has to be higher than Q_{1st} and Q_{2nd} to achieve the noise cancelling effects. Further, Q_{1st} is effective in lowering the combustion noise at around 1500 Hz.

Figure 26. The length of time in crank angle between the peaks of the rates of the pressure rise in Peaks 2 and 3 ($dP/d\theta_{2-3}$) vs overall combustion noise

The length of time in crank angle between the peaks of the rate of pressure rise in Peaks 1 and 2 ($dP/d\theta_{1-2}$) and the length of time in crank angle between the peaks of the rate of pressure rise in Peaks 2 and 3 ($dP/d\theta_{2-3}$) were changed maintaining the

$Q_{1st}:Q_{2nd}:Q_{3rd}=195J:155J:235J$, as shown in Figure 27. The combustion noise was the lowest when the $dP/d\theta_{1-2}=dP/d\theta_{2-3}=3$ CA.

Figure 27. Effects of the length of time in crank angle between the peaks of the rates of pressure rise in Peaks 1 and 2 ($dP/d\theta_{1-2}$) and between the peaks of the rates of pressure rise in Peaks 2 and 3 ($dP/d\theta_{2-3}$) on overall combustion noise

Table 4 shows the amplifying frequency (light blue column) and cancelling frequency (light yellow column) versus the length of time in crank angle between the peaks of the maximum rates of pressure rise (Δt). When $\Delta t=3$ CA, the amplifying frequencies are 8000 Hz and 4000 Hz, higher than 3000 Hz and the cancelling frequency (2000 Hz) is in the range of 600-3000 Hz where the human ear is sensitive to sound (Figure 5); however, for $\Delta t=4$ CA and 5 CA, there are amplifying frequencies in the 600-3000 Hz range (pink column in Table 4).

This is a reason why the combustion noise at $\Delta t=3$ CA (black line) is the lowest in Figure 27.

Figure 28 plots the overall combustion noise versus the indicated thermal efficiency for all the plots in Figure 26. The combustion noise was the lowest at Point B (plot with light green square) 87.1 dBA maintaining 50.3 % thermal efficiency, and the combustion noise increased with the increase in the length of time in crank angle between the peaks of the rate of pressure rise in Peaks 2 and 3 ($dP/d\theta_{2-3}$), as shown by the black dotted arrow in Figure 26.

Figure 28. Overall combustion noise vs indicated thermal efficiency for the plots in Figure 26

From these simulation results, the Point B is the optimum condition for low combustion noise maintaining a high thermal efficiency, and Figure 29 shows the histories of the rate of heat release and pressure rise at Point B.

Figure 29. Histories of the rates of pressure rise and heat release at Point B in Figure 28

Test 4: Evaluation of Accuracy of the Simulation Results in Test 3 by Engine Tests

With the test engine, the first and second heat releases show premixed diesel combustion, however the third heat release may become diffusion combustion in the three stage combustion. To further elucidate this, the engine was operated with three types of two stage combustion (Twin₁₋₂, Twin₂₋₃, and Twin₁₋₃), as shown in Figure 15, and the effects of the three stage combustion on the combustion noise reduction in these three cases was investigated.

The cylinder pressure level of each of the two stage combustion tests is shown in Figure 30. In the simulation Figure 24, the amplifying and reduction frequencies of Twin₁₋₃ are around 2000 Hz and 1000 Hz respectively, and in the engine tests, the amplifying and reduction frequencies of Twin₁₋₃ are around 2000 Hz and 900 Hz respectively. The amplifying frequency of Twin₁₋₃ overlaps the reduction frequency of Twin₁₋₂ and Twin₂₋₃, and here combustion noise reduction in the three stage combustion can be expected in the engine test.

Figure 30. Cylinder pressure level of three sets of two stage heat releases, Twin₁₋₂, Twin₂₋₃ and Twin₁₋₃, (Engine test)

Test 5: Effects of Multistage Combustion on the Indicated Thermal Efficiency and Combustion Noise (Simulation)

The optimum histories of the heat release rates for low combustion noise and high thermal efficiency were calculated by simulations in single, two, and three stage combustions. Further, the three stage combustion was synthesized from the heat release histories of Twin₁₋₂ and Twin₂₋₃ of the engine test data in Figure 15, termed the “synthesized three stage combustion from engine data”. The heat release histories are shown in Figure 31, and the frequency characteristics of the overall combustion noise are shown in Figure 32.

The large reduction in overall combustion noise maintaining the high degree of constant volume can be achieved with increases in the number of fuel injections near the TDC, however if the number of fuel injections is higher than four, a deterioration in the degree of constant volume becomes an issue of concern, as the combustion after top dead center becomes diffusion combustion.

Figure 32. Plots of frequency characteristics of overall combustion noise

Conclusions

This paper investigates combustion noise reduction maintaining high thermal efficiency by multiple fuel injections with numerical simulations and engine tests. The conclusions of the investigations may be summarized as follows:

1. Multiple fuel injections near top dead center is effective for combustion noise reduction maintaining a high degree of constant volume, because of the reduction in the maximum rates of heat release in each heat release and the noise reduction effect by the noise cancelling spike (NCS) combustion. The NCS processes become increasingly complex with more fuel injections, and the amplifying and canceling frequencies can be controlled by the length of time in crank angle between the peaks of the rates of pressure rise.
2. In the late two stage combustion, the combustion noise reduction was most effectively achieved when the heating value of Q_{2nd} is higher than that of Q_{1st} , because the Q_{2nd} heat release occurs during the expansion stroke and much energy is required for Q_{2nd} to be able to reduce the combustion noise generated by the Q_{1st} heat release. However, in the early two stage combustion, the Q_{1st} heat release occurs during the compression stroke and the combustion noise reduction by the early two stage NCS combustion is more effective than the combustion noise reduction by the late two stage NCS combustion.
3. In the three stage combustion, the first heat release is effective in lowering the combustion noise around 1500 Hz, and the third heat release must be the largest of the three heat releases to reduce the combustion noise by the NCS effects.
4. With the results of three stage combustion at the 0.6 MPa IMEP and 2000 rpm condition, the optimum heat release shape for the lowest combustion noise and higher indicated thermal efficiency is shown in Figure 28. The heating values of Q_{1st} , Q_{2nd} , and Q_{3rd} are 195 J, 155 J, and 235 J respectively, and the length of time in crank angle between the peaks of the rate of $dP/d\theta_{1,2}$ and $dP/d\theta_{2,3}$ were 3 CA. The combustion noise and the indicated thermal efficiency were 87.1 dBA and 50.3 % respectively.
5. A large reduction in overall combustion noise maintaining a high degree of constant volume can be achieved with increases in the number of the fuel injections near top dead center, however with more than four fuel injection, the deterioration in the degree of constant volume becomes an issue of concern, as the combustion after top dead center becomes diffusion combustion.

Appendices

Appendix 1: The Basis of the Coherent Method for the Combustion Noise Calculation

In this paper, the combustion noise was calculated by the coherent method, and the following describes the basis for the coherent method. The following is the parameters involved.

$h(t)$: Transfer characteristics of the engine

$x(t)$: In-cylinder pressure (input)

$y(t)$: Engine noise (combustion noise plus other noises (mainly mechanical noise)) (output)

$u(t)$: Other Noises, noise other than the combustion noise

The $x(t)$ and $y(t)$ are measurable parameter variables.

Figure 3 shows the combustion noise generation mode and the in-cylinder pressure $x(t)$ is transformed to combustion noise via $h(t)$. The engine noise $y(t)$ can be expressed as in equation a-1

$$y(t) = h(t) * x(t) + u(t) \quad (a-1)$$

With Fourier transformation on both sides and

$$Y(k) = H(k) * X(k) + U(k) \quad (a-2)$$

the transfer characteristic $H(k)$ can be defined by equation a-3.

$$H(k) = W_{xy}(K)/W_{xx}(k) \quad (a-3)$$

W_{xx} : Power spectrum by the FFT analysis of the in-cylinder pressure waveform

W_{xy} : Cross power spectrum by the FFT analysis of the sound pressure of the engine noise level and pressure waveform

The coherent combustion noise $CCNL(k)$ can be calculated from the transfer characteristic $H(k)$ and cylinder pressure level $X(k)$ as in equation a-4, and then the A weighted sound pressure level applied.

$$CCNL(k) = H(k) * X(k) \quad (a-4)$$

$CCNL(k)$: Coherent combustion noise

Then, the engine structure attenuation can be calculated from equation a-5.

$$SA(k) = CCNL(k) - X(k) \quad (a-5)$$

$SA(k)$: Structure attenuation

In the simulation, the in-cylinder pressure history was calculated from the heat release history by the Runge-Kutta numerical method and the combustion noise $CNL(k)$ can be calculated from the structure attenuation $SA(k)$ and in-cylinder pressure level $X(k)$ by equation a-5.

$$CNL(k) = SA(k) + X(k) \quad (a-6)$$

$CNL(k)$: Combustion noise level

Overall, when the structure attenuation has been obtained, the combustion noise can be calculated from the in-cylinder pressure data.

Appendix 2: The Diffusion Combustion of the Third Heat Release in the Three Stage Combustion

As shown in Figure AP-1 for the three stage combustion, the first and second heat releases in the test engine show premixed diesel combustion and the third heat release shows diffusion combustion. This is because available oxygen in the cylinder has been consumed by the first and second heat releases. To make the premixed combustion in the third heat release, the boosted pressure is increased and the fuel ratio for the three injections was varied. Figure AP-2 shows the results, here premixed combustion in the third heat release has been achieved, and the operational range of the three stage premixed diesel combustion is now under investigation.

Figure AP-1. Heat release shape of three stage combustion in the case of diffusion combustion in the Q_{3rd}

Figure AP-2. Heat release shape of three stage combustion in the case of premixed combustion in the Q_{3rd}
