Abstract

A series of surface-doped LiMn$_2$O$_4$ samples modified by a Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution were synthesized using a simple and facile sol-gel method to achieve the enhanced cycling performance, especially at elevated temperatures. The corresponding phase structure and morphology were investigated by X-ray diffraction (XRD) and scanning electron microscopy (SEM), respectively. The modified layer on the surface of LiMn$_2$O$_4$ particles, featuring a LiNi$_{\delta}$Mn$_{2-\delta}$O$_4$-like phase, together with a Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution, as confirmed by XRD and transmission electron microscopy (TEM), plays a key role in alleviating the dissolution of manganese, thus enhancing the cycling performance and rate capability relative to bare LiMn$_2$O$_4$. The 0.5 wt.%-modified LiMn$_2$O$_4$ sample delivers a discharge capacity of 113 mAh g$^{-1}$ and a capacity retention of 93.2% following 300 cycles at 1 C and 25 °C, which is higher than the values of 96 mAh g$^{-1}$ and 81.2% for bare LiMn$_2$O$_4$. In addition, at 55 °C, a capacity retention of 81.2% at 1 C is obtained for the 0.5 wt.%-modified LiMn$_2$O$_4$ sample after 200 cycles, compared to 70.0% for bare LiMn$_2$O$_4$. Modifying the surface of the latter by a LiNi$_{\delta}$Mn$_{2-\delta}$O$_4$-like phase mixed with a Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution, is an effective strategy for improving electrochemical properties.

Keywords: LiMn$_2$O$_4$, cathode, surface modification
1. Introduction

The use of rechargeable Li-ion batteries as a most promising power source for the electric (EVs) and hybrid electric vehicles (HEVs) has attracted increased interest. The cathode material plays a vital role in rechargeable Li-ion batteries owing to its decisive contribution to safety, low cost, and high power/energy densities [1]. Amongst the layered LiCoO$_2$, LiNiO$_2$, LiNi$_{1/3}$Co$_{1/3}$Mn$_{1/3}$O$_2$, and spinel LiMn$_2$O$_4$ oxide cathode materials, the latter is an attractive and promising candidate due to its low cost, environmental friendliness, abundant resource, easy preparation, high rate capability, and high thermal stability [2–4]. However, LiMn$_2$O$_4$ often exhibits rapid capacity fading during the charge/discharge process, especially at the elevated temperatures, hindering broad commercial applications. The above problem mainly results from the lattice instability due to the Jahn-Teller effect and the dissolution of lattice manganese in the electrolyte due to the disproportion reaction of Mn$^{3+}$ caused by traces of HF in the electrolyte, with the latter reaction being more important for capacity fading [4–6].

Although cationic doping of Mn sites by Ni$^{2+}$ [7,8], Al$^{3+}$ [9,10], Ru$^{4+}$ [11], Ni-Cu [12], Mg-Si [13], and La-Bi [14], has been carried out to retard capacity fading, the irreversible capacity loss arising from the dissolution of manganese cannot be completely alleviated both at room and elevated temperatures [15]. Surface modification, being another effective approach, is drawing more interest, since it can give rise to improved electrochemical properties due to its protective effect at the cathode/electrolyte interfaces, not only suppressing the dissolution of manganese, but also
improving operation safety and structural stability [16,17]. Many compounds, such as metal oxides [18,19], fluorides [20,21], and phosphates [22,23], have been exploited as surface-modifying materials for upgrading the electrochemical performance of spinel LiMn$_2$O$_4$. However, these materials often fail to improve the capacity and rate capability owing to the inferior Li$^+$ migration and/or electron conductivity of the inert layer [24,25]. Recently, modification of LiMn$_2$O$_4$ by a layer of media containing Li$^+$ ions and/or electron conductors such as LiNbO$_3$ [1], LiNi$_{0.5}$Mn$_{1.5}$O$_4$ [26,27], Li$_2$ZrO$_3$ [28], Li$_{1.15}$Co$_{0.32}$Mn$_{1.53}$O$_4$ [29], and Li$_4$Ti$_5$O$_{12}$ [30], was used to improve electrochemical properties by accelerating Li ions transport and/or the charge transfer on the surface of the cathode material. Li$_2$CuO$_2$, exhibiting an $Immm$ orthorhombic phase, possesses a relatively large amount of lithium per unit formula, with the lithium ions located between one-dimensional chains of edge-sharing [CuO$_4$] square planar units, facilitating rapid transfer of Li$^+$ ions [31,32]. Li$_2$CuO$_2$ delivers a high capacity of 200 mAh g$^{-1}$ and an average discharge voltage of 2.5 V, along with undamaged one-dimensional [CuO$_4$] chains during cycling [33]. Unfortunately, Li$_2$CuO$_2$ exhibits poor lithiation reversibility and a capacity loss during the charge/discharge process [34]. These drawbacks can be retarded by substitution of Cu for Ni, resulting in a Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution due to their isostructure [32,35]. Li$_2$Cu$_{0.5}$Ni$_{0.5}$O$_2$, a solid solution of equivalent amounts of Li$_2$CuO$_2$ and Li$_2$NiO$_2$ proposed by Imanishi et al. [30], displays a maximum capacity of 250 mAh g$^{-1}$ at a current density of 0.6 mA cm$^{-2}$ in the range of 1.5–4.0 V, together with good reversibility during charge/discharge cycling, as compared with that of pure Li$_2$CuO$_2$ and Li$_2$NiO$_2$. Ruther et al.
also investigated the structure and electrochemical performance of Li$_2$Cu$_{0.5}$Ni$_{0.5}$O$_2$, which retained its stable structure even after extraction of one lithium per formula unit [36]. A lack of studies on Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solutions acting as the surface-modifying materials, appears more important for cathode materials in rechargeable Li-ion batteries based on above merits. On the other hand, surface-doping, i.e., the incorporation of cations into the surface within a depth of several nanometers, has been exploited as an interesting technique to improve cycling performance [37]. LiMn$_2$O$_4$ modified by a LiMn$_{2-x}$Ti$_x$O$_4$ surface layer displays a remarkably improved cycling performance due to the electrochemical activity of the latter, maintaining the ion/charge transport channels on the surface and minimizing the possible phase segregation owing to structural similarity [37]. LiCu$_x$Mn$_{2-x}$O$_4$-coated LiMn$_2$O$_4$ exhibits improved electrochemical properties, especially at high current densities, attributed to the significant reduction of side reactions and Mn dissolution at the cathode/electrolyte interface [38]. LiMn$_2$O$_4$ surface-modified by LiNi$_{0.05}$Mn$_{1.95}$O$_4$, prepared by a tartaric acid gel process, exhibits high capacity retention (96%) after 20 cycles, compared to a value of 89% for unmodified LiMn$_2$O$_4$ at 0.5 C, which is ascribed to the unblocked insertion/extraction of Li [39]. The Ni-doped layer on the surface of LiMn$_2$O$_4$ particles, is expected to improve their electrochemical performance. Hence, LiMn$_2$O$_4$ surface-modified with LiNi$_{0.05}$Mn$_{1-x}$O$_4$ together with the Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution, was used to improve electrochemical performance.

In this work, solution combustion synthesis (SCS), a highly exothermic and self-sustaining
reaction, was employed to prepare LiMn$_2$O$_4$ powders, yielding nano-sized particles with high specific areas to facilitate the electrochemical properties [40,41]. The modified LiMn$_2$O$_4$ samples were prepared by a simple and facile sol-gel method to ensure uniformity of the modified layers. The phase structure, morphology, and electrochemical performance at 25 and 55 °C, were investigated and discussed in detail.
2. Experimental

2.1 Preparation and characterization of surface-doped LiMn$_2$O$_4$ modified by a Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution.

LiMn$_2$O$_4$ powders were prepared by SCS with subsequent calcination [41–43]. The following raw materials were used without further purification: lithium nitrate (LiNO$_3$, 99.0%, Kishida Chemical Co., Ltd., Japan), lithium acetate (CH$_3$COOLi, 99.0%, Kishida Chemical Co., Ltd., Japan), manganese nitrate (Mn(NO$_3$)$_2$, 50% w/w aqueous solution, Alfa Aesar), nickel nitrate (Ni(NO$_3$)$_2$·6H$_2$O, 99.9%, Wako Pure Chemical Industries, Ltd., Japan), copper nitrate (Cu(NO$_3$)$_2$·3H$_2$O, 99.0–104.0%, Wako Pure Chemical Industries, Ltd., Japan), and urea (NH$_2$CONH$_2$, 99.0%, Chameleon Reagent, Japan). LiNO$_3$, Mn(NO$_3$)$_2$ (Li:Mn mole ratio = 1.05:2), and NH$_2$CONH$_2$ ($\phi = 0.5$, where $\phi$ is the ratio of total valency of urea to total valency of nitrate), were dissolved in distilled water. The homogenous viscous sol-gel formed after evaporating water, was subjected to combustion in a home-made apparatus. The collected powders were subsequently calcined in air at 800 °C for 24 h to obtain LiMn$_2$O$_4$ powders.

Surface-doped LiMn$_2$O$_4$ samples modified by a Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution were prepared utilizing a facile sol-gel method. CH$_3$COOLi, Ni(NO$_3$)$_2$, and Cu(NO$_3$)$_2$ were dissolved in distilled water under stirring (in amounts required by equimolar Li$_2$CuO$_2$ and Li$_2$NiO$_2$) to form a homogenous solution. The obtained solution was dropwise added to an aqueous dispersion of
LiMn$_2$O$_4$ obtained by ultrasonication. Finally, the modified LiMn$_2$O$_4$ powders were calcined in air at 600 °C for 3 h. A series of 0, 0.5, 1.0, and 2.0 wt.%-modified samples were prepared, denoted as 0, 0.5, 1.0, and 2.0 wt.% for simplicity, respectively.

Powder X-ray diffraction (XRD, Cu Ka, Rigaku Miniflex600), and scanning electron microscopy (SEM, JEOL, JSM-7001FA) together with transmission electron microscopy (TEM, JEOL, JEM-2010F) were employed to identify the phase structure and characterize the morphology, size, and modified sample layers, respectively. X-ray photoelectron spectroscopy (XPS, JEOL Ltd., JPS-9200) using an Mg Ka X-ray source was used to detect the surface composition.

2.2 Cell assembly and electrochemical measurements.

A Swagelok-type cell was assembled in an Ar-filled glove box [43,44]. The working electrode was prepared by combining 80 wt.% active material, 10 wt.% binder (PVDF) dissolved in N-methyl-2-pyrrolidone (NMP), and 10 wt.% conductive carbon (acetylene black). A lithium metal disk served as the counter and reference electrode. A 1 M lithium hexafluorophosphatate (LiPF$_6$) in ethylene carbonate (EC)/dimethyl carbonate (DMC) (1:1 in volume) was used as an electrolyte, and a Celgard polypropylene membrane served as separator. Electrochemical measurements at 25 and 55 °C were galvanostatically conducted in a voltage range of 3.2–4.4 V (at a rate of 1 C, corresponding to the full charge/discharge of 150 mAh g$^{-1}$ in 1 h) using a battery tester (Arbin Instruments, MSTAT4, USA). Cyclic voltammetry (CV) was performed using a
potentiostat/galvanostat (Autolab, PGSTAT128N) in a range of 3.2–4.4 V at a scan rate of 0.1 mV·s⁻¹. Electrochemical impedance spectroscopy (EIS) was conducted employing an Autolab instrument with a frequency response analyzer (FRA), in the frequency range from 1000 kHz to 0.01 Hz.
3. Results and discussion

Figure 1 displays the XRD patterns of modified LiMn$_2$O$_4$ samples. To monitor the shift of the diffraction peaks after modification, silicon was employed as a reference and calibrant. The diffraction peaks of all samples, except those of silicon, are indexed to the standard spinel LiMn$_2$O$_4$, belonging to the $Fd3m$ space group. No diffraction peaks of the Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution are observed, which is ascribed to their low amount and/or amorphous structure [15]. A gradual shift to higher $2\theta$ values is observed for the enlarged diffraction peak of (111) with increasing degree of modification, indicating a shrinking lattice parameter. The lattice parameter and cell volume refined by MDI Jade software are shown in Table 1. It is thought that the substitution of Mn$^{3+}$ by Ni$^{2+}$ results in a decreased lattice parameter, mainly due to the stronger Ni-O bonds compared to Mn-O bonds, despite the small difference in the ionic radii of Mn$^{3+}$ (0.65 Å) and Ni$^{2+}$ (0.69 Å) [45–47]. The decreased lattice parameter in this work is deemed to be attributed to the diffusion of a small amount of Ni to the surface of the host spinel particles to form a LiNi$_{0.05}$Mn$_{1.95}$O$_4$-like phase, in agreement with the slight shift of the (111) diffraction peak of LiMn$_2$O$_4$ surface-modified by LiNi$_{0.05}$Mn$_{1.95}$O$_4$ to higher $2\theta$ values [39]. On the other hand, we suppose that Cu$^{2+}$ diffuses into the host spinel particles to substitute Mn$^{3+}$, which is expected to result in an increased lattice parameter due to the larger ionic radius of Cu$^{2+}$ (0.87 Å) compared to that of Mn$^{3+}$ (0.65 Å), coinciding with
the increased lattice parameters of LiCu$_3$Ni$_{2-x}$O$_4$ coated LiMn$_2$O$_4$ [38]. The LiNi$_3$Mn$_{2-\delta}$O$_4$-like phase (detectable by TEM in 2.0 wt.% sample) is produced on the surface of the host spinel particles after the diffusion of a small amount of Ni, not Cu, during calcination at 600 °C for 3 h, benefiting the electrochemical properties.

Figure 2 shows SEM images of modified LiMn$_2$O$_4$ samples. Primary particles of 200‒500 nm size (Fig. 2 inset) agglomerate to form secondary particles with sizes of < 10 μm. The images display similar particle shapes and sizes for all samples, indicating no significant morphology changes after modification. The detection of the modified layers on the surface of LiMn$_2$O$_4$ particles was performed by TEM images of 0.5 and 2.0 wt.% samples (Fig. 3). A modified layer is invisible on the surface of the 0.5 wt.% sample (Fig. 3 (a)) due to its low amount, whereas that is noticeable on the spinel particle surface for the 2.0 wt.% sample. Interestingly, electron diffraction patterns in the selected area of the modified layer for the 2.0 wt.% sample, were similar but not identical to those of the spinel structure, since the obtained lattice distance of 0.46 nm is slightly lower than the lattice fringe distance of 0.48 nm for the (111) plane of the spinel structure, corresponding to the shift of (111) XRD diffraction peak to higher angles. The above finding is thought to be due to the produced LiNi$_3$Mn$_{2-\delta}$O$_4$-like phase, not the Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution due to the absence of the characteristic $d$-spacing of around 0.34 nm [36]. The Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution mixed with the LiNi$_3$Mn$_{2-\delta}$O$_4$-like phase in the modified layer, probably exhibits an amorphous structure based on a number of small modified layer areas with undetectable electron diffraction patterns [43].
order to identify the presence of Cu and Ni in the modified layer, the cross section of the 0.5 wt.% sample was characterized by energy dispersive X-ray spectrometry (EDS). The particles were embedded within resin, and the cross section was obtained after mechanical and Ar-ion milling, as shown in Fig. 3 (c). EDS spectra collected from regions 1 (resin) and 2 (resin-particle boundary) (Fig. 3 (d)) is displayed in Fig. 3 (e). The carbon signal originates from the resin, while that of Mo is due to the substrate. Compared with region 1, obvious peaks of Ni and Cu are observed in region 2, indicating the presence of Ni and Cu elements in the surface of the particles.

XPS is always used to determine the surface composition and chemical states of ions. Figure 4 displays the Mn, Cu, Ni 2p\textsubscript{3/2} peaks for 0 and 0.5 wt.% samples. XPS binding energy of Mn 2p\textsubscript{3/2} peaks is located at 642.2 and 642.5 eV for 0 and 0.5 wt.% samples, respectively, which these values are in the range of 614.9 eV (Mn\textsuperscript{3+}) to 642.6 eV (Mn\textsuperscript{4+}) [48,49]. The relative amount of Mn\textsuperscript{4+} is increased from 50.1% for 0 wt.% to 65.1% for 0.5 wt.% sample after splitting Mn 2p\textsubscript{3/2} peak. The more relative amount of Mn\textsuperscript{4+} for 0.5 wt.% will result in a higher average Mn valence of approximately 3.66 than 3.51 for 0 wt.% sample. This can be attributed to the small substitution of Mn by Ni to form LiNi\textsubscript{\delta}Mn\textsubscript{2-\delta}O\textsubscript{4}-like phase, expecting to improve the cycling performance due to increased structure stability. Compared with 0 wt.% sample, 0.5 wt.% sample shows an obvious Cu 2p\textsubscript{3/2} peak located at 933.6–935.2 eV, which is higher than 933.6 eV value (CuO) [50]. The higher Cu 2p\textsubscript{3/2} binding energy was the major XPS characteristic of CuO, indicating the presence of Cu\textsuperscript{2+} at the surface of particles [51,52]. The Ni 2p\textsubscript{3/2} peaks with binding energy of 854.1 eV (NiO) [53] is
hardly observed for the modified sample, which is likely due to a mount of Ni diffusion into the spinel matrix to substitute Mn.

Figure 5 shows the discharge capacity as a function of cycle number for modified LiMn$_2$O$_4$ samples at 1 C and 25 °C. Bare LiMn$_2$O$_4$ shows a significantly decreased discharge capacity (96 mAh g$^{-1}$) with a capacity retention of 81.2% at 1 C after 300 cycles, whereas modified LiMn$_2$O$_4$ samples exhibit a remarkably enhanced cycling performance. The 0.5, 1.0, and 2.0 wt.% samples deliver discharge capacities of 113, 111, 103 mAh g$^{-1}$, with capacity retention values of 93.2, 95.0, and 96.3% after 300 cycles, respectively. Moreover, since degree of modification increase in the order of 0.5, 1.0, and 2.0 wt.%, a capacity fading of 0.027, 0.019, 0.013 mAh g$^{-1}$ per cycle is displayed, compared to 0.074 mAh g$^{-1}$ per cycle for bare LiMn$_2$O$_4$. The improved cycling performance is due to suppressed dissolution of Mn in the electrolyte and the increased stability of the spinel structure after modification.

Figure 6 shows the rate capability of modified LiMn$_2$O$_4$ samples at 25 °C. An obviously decreased capacity at increased current densities is observed for bare LiMn$_2$O$_4$, which displays the lowest discharge capacity of 82 mAh g$^{-1}$ among all samples at 7 C. This can be rationalized by the great battery polarization resulting from the limited Li-ion diffusion during cycling, as compared to the modified samples [54]. In particular, the 0.5 wt.% sample delivers the best rate capability, showing a discharge capacity of 120 mAh g$^{-1}$ at 1 C, 115 mA h g$^{-1}$ at 2 C, 111 mA h g$^{-1}$ at 3 C, 107 mAh g$^{-1}$ at 4 C, 103 mAh g$^{-1}$ at 5 C, and 95 mAh g$^{-1}$ at 7 C. Compared to bare LiMn$_2$O$_4$, the above
sample recovers its high capacity after discharging at 7 C and displays a smaller capacity difference between 1 to 2 C. The capacity retention (relative to 1 C) is increased in the order of 0 wt.% < 0.5 wt.% < 1.0 wt.% < 2.0 wt.% at the corresponding current densities. This increased capacity retention of modified samples indicates higher lithium and/or electron conductivity compared with the bare LiMn2O4.

High electrochemical performance at elevated temperatures is critical for commercial usage of spinel LiMn2O4 cathodes in rechargeable Li-ion batteries. Figure 7 displays the dependence of discharge capacity on the number of cycles for modified LiMn2O4 samples at 1 C and 55 °C. Bare LiMn2O4 displays a significantly decreased capacity after cycling at 1 C and 55 °C, maintaining a discharge capacity of only 83 mAh g⁻¹ after 200 cycles. A remarkably enhanced cycling performance is achieved for the modified LiMn2O4 samples. Improved capacity retention values of 81.2, 81.2, and 92.2% after 200 cycles are obtained for 0.5, 1.0, and 2.0 wt.% samples, respectively, compared to the value of 70.0% for bare LiMn2O4. These higher capacity retentions at 55 °C and 1 C, than 80% of LiNi₀.₂Mn₁.₈O₄ at 60 °C and 0.1 C after 100 cycles [8], confirm the cycling stability of modified LiMn2O4. An improved capacity retention at 55 °C, which is coinciding with that at 25 °C, is observed for the higher degrees of modification that result in a lesser extent of manganese dissolution and more stable spinel structure, thereby enhancing cycling performance [43].

Figure 8 shows the charge-discharge curves of modified LiMn2O4 samples at 1 C and 55 °C. Two obvious plateaus are observed for all samples, indicating two oxidation/reduction reactions during
Li extraction/insertion. The plateaus at 4.0–4.1, and 3.9–4.0 V, correspond to the MnO2/Li0.5Mn2O4, and Li0.5Mn2O4/LiMn2O4 phase transitions, respectively [55,56]. A small voltage difference between the charge and discharge plateaus is obtained for the modified samples in comparison with bare LiMn2O4, indicating smaller battery polarization [27]. The modified LiMn2O4 samples exhibit a smaller initial capacity loss after 200 cycles and better cycling performance.

In order to clearly understand the oxidation/reduction of cathode materials during cycling, CV curves of modified LiMn2O4 samples were recorded (Fig. 9). Two pairs of peaks, corresponding to the two charge-discharge plateaus in Fig. 8, indicate two reversible redox reactions during Li extraction/insertion. The unchanged CV curves of the modified samples, as compared with those of bare LiMn2O4, confirm that modification does not affect the electrochemical process of spinel LiMn2O4. The potential values of the first CV curve cycle are shown in Table 2. The 0.5, 1.0, and 2.0 wt.% samples exhibit higher cathodic peaks of 3.96/4.07, 3.96/4.08, and 3.97/4.10 V, respectively, than bare LiMn2O4 (3.93/4.06 V). This indicates that the modified samples can supply an improved operating voltage during the discharge process in comparison with the unmodified LiMn2O4. Note that \( \Delta E_p \) is the potential difference between the anodic \( (E_{pa}) \) and cathodic \( (E_{pc}) \) peaks. The values of \( E_{p1}/E_{p2} \) decrease in the order of 0 wt.% > 0.5 wt.% > 1.0 wt.% > 2.0 wt.%, being equal to 0.14/0.14, 0.12/0.14, 0.12/0.12, and 0.08/0.08 V, respectively. These values indicate a weaker polarization and easier extraction/insertion of Li ions for the modified samples [57]. The modified material can alleviate the dissolution of Mn and preserve the stable structure of the spinel.
LiMn₂O₄ during Li extraction/insertion.

The rate capability of 0 and 0.5 wt.% samples at 55 °C is shown in Fig. 10 (a). Compared with bare LiMn₂O₄, the modified sample exhibits improved rate capability at high temperature. The 0.5 wt.% sample delivers a high discharge capacity of 96 mAh g⁻¹ and a capacity retention of 78.7% (relative to 1 C), compared with the respective values of 89 mAh g⁻¹ and 71.4% for the 0 wt.% sample at 7 C. The former sample exhibits a lesser capacity fading than bare LiMn₂O₄ at 1, 2, and 3 C, together with that at 1 and 2 C in recovered stage after 60 cycles. This indicates that the modifying material can effectively suppress the dissolution of manganese and preserve structural stability even at high temperature. Figure 10 (b) shows the discharge curves of the first cycle at different current densities for 0 and 0.5 wt.% samples at 55 °C. The solid line corresponds to the 0.5 wt.% sample, while the dished line represents the 0 wt.% sample. Compared to bare LiMn₂O₄, the modified sample still delivers similar high voltages at different current densities, indicating that modification can result in unimpaired voltage during the discharge process. The above voltage is decreased with increasing current densities. The shape of the discharge curves gradually transforms from two obvious plateaus at 1, 2, and 3 C into a slopping line at 4, 5, and 7 C, demonstrating the ohmic drop and increased cell polarization at high current densities [58].

EIS is an important tool to investigate the electrochemical properties of electrodes. Figure 11 displays the Nyquist plots of modified LiMn₂O₄ samples after 200 cycles at 1 C and 55 °C, along with the equivalent circuit in the inset used to fit the spectra. As shown in the equivalent circuit, $R_s$
is the ohmic resistance that includes electrolyte and electrode resistance, $R_f$ represents the resistance of Li-ion diffusion in the surface layer (solid electrolyte interphase (SEI) film and modified layer), and $R_{ct}$ is the charge transfer resistance. Constant phase elements, $CPE_1$ and $CPE_2$, denote the capacitance of the SEI film and the double layer, respectively. $CPE_3$ is chosen instead of the finite Warburg element to properly fit the Nyquist plots in the low-frequency region [59]. The EIS data simulated by Zsimpwin software are listed in Table 3. A large $R_f$ value of 27.01 $\Omega$ and $R_{ct}$ value of 75.60 $\Omega$ are obtained for bare LiMn$_2$O$_4$, decreasing after the modification. The decreased $R_f$ and $R_{ct}$ values indicate that the modified layer can alleviate the side reactions at the electrode/electrolyte interface to improve the cycling performance by suppressing SEI film formation and enhancing charge transport [60]. In particular, the lowest $R_f$ and $R_{ct}$ values of 6.54 and 49.23 $\Omega$ are achieved for the 0.5 wt.% sample. As the degree of modification increases, so do $R_f$ and $R_{ct}$, which is consistent with our previous report and can be attributed to the dominant role of hindered Li-ion diffusion via the thick modified layer due to the increased Li-ion diffusion path, regardless of the enhanced Li-ion diffusion via the retarded SEI film [43].

To detect the effect of the modified layer on the structural stability of spinel LiMn$_2$O$_4$, an investigation of the cycled electrode morphology was carried out. Figure 12 displays SEM images of the cycled electrodes for 0 and 0.5 wt.% samples, before cycling (a) and (b), and after 300 cycling (c) and (d) at 1 C and 25 °C, respectively. Compared to Fig. 12 (a), an obvious large crevice, along with the small crevice on the particles shown in the inset, is observed after 300 cycles for the
0 wt.% sample in Fig. 12 (c), arising from the erosion by HF in the electrolyte and the inferior stability of the spinel structure [61]. No morphology changes are noticed for the 0.5 wt.% sample before cycling (Fig.11 (b)) and after 300 cycles (Fig. 12 (d)), reflecting the fact that the protective modified layer can restrain the electrolyte erosion and preserve structural stability, resulting in improved cycling performance.
4. Conclusions

Surface-doped LiMn$_2$O$_4$ modified by a solid solution of Li$_2$CuO$_2$-Li$_2$NiO$_2$ was synthesized by a simple and facile sol-gel method. XRD and SEM confirmed the presence of a LiNi$_{\delta}$Mn$_{2-\delta}$O$_4$-like phase (detectable by TEM), and the similar morphology, respectively. The electrochemical properties at 25 and 55 °C, in particular the cycling performance, were improved for the modified LiMn$_2$O$_4$ samples. Following 300 cycles at 25 °C, a high capacity retention of 93.2% and a discharge capacity of 113 mAh g$^{-1}$, were delivered by the 0.5 wt.% sample at 1 C, compared with the respective values of 81.2% and 96 mAh g$^{-1}$ for the bare LiMn$_2$O$_4$. After 200 cycles at 55 °C, a remarkably improved capacity retention of 81.2% was exhibited by the 0.5 wt.% sample, being higher than the value of 70.0% for bare LiMn$_2$O$_4$ at 1 C. The enhanced cycling performance is attributed to the modified layer, which acts as a protecting medium to suppress the dissolution of manganese and support the structural stability, along with the intrinsic character of allowing the effective mobility of Li ions. The LiNi$_{\delta}$Mn$_{2-\delta}$O$_4$-like phase together with the Li$_2$CuO$_2$-Li$_2$NiO$_2$ solid solution can be considered appropriate candidates for surface modification to obtain enhanced electrochemical properties of spinel LiMn$_2$O$_4$.

Fig. 9

The figure shows cyclic voltammetry (CV) plots for different concentrations of a material under study. The concentration levels are 0 wt.%, 0.5 wt.%, 1.0 wt.%, and 2.0 wt.%. The x-axis represents the potential (V vs. Li/Li⁺), and the y-axis represents the current density (A.g⁻¹). The plots compare the current density for the 1st cycle and the 5th cycle for each concentration level.
