19 **Abstract**

20 Hydrographic conditions and distributions of juvenile temperate seabass *Lateolabrax japonicus* were
21 observed in early spring from 2009 to 2012 in the Yura River estuary, which is highly stratified due to its small
22 tides and consequent seawater intrusion into the bottom layer of the river as a saltwedge. In all four studied years,
23 the upstream expansion of their distribution coincided with the timing of the saltwedge intrusion from the lower
24 to upper estuary, indicating that juvenile fish used saltwedge intrusions to ascend the estuary in early spring.
25 However, juveniles sometimes remained in the nearshore area even when the saltwedge intrusion had already
26 occurred, indicating that other triggers are also likely to be necessary. We therefore evaluated the effects of
27 temperature on upstream migration behaviours. The relationship between the mean temperature they experienced
28 from hatch until starting the ascent and mean age of each cohort at the upstream migration was fitted in the law of
29 effective cumulative temperature. Most cohorts ascended the river at an effective cumulative temperature of
30 approximately 500°C-days. This suggests that higher temperatures would lead to a shorter period prior to the
31 upstream migration.

45 **Introduction**

46

47 Temperate seabass *Lateolabrax japonicus* is an important euryhaline species for Japanese coastal fisheries (Shoji
48 et al. 2002). Its utilization of the “coastal ecosystem complex” is characterized as follows; 1) ontogenetic shift of
49 habitats and 2) parallel utilization of various habitats. This fish is known to change its habitats ontogenetically
50 during the early life history as well as other coastal fishes. Temperate seabass usually spawn offshore (around
51 and outside of the bay mouth) during the winter season (Kuwatani 1962, Watanabe 1965, Hayashi and Kiyono
52 1978, Hibino et al. 2007). The planktonic larvae are transported onshore (Ohmi 2002, Hibino et al. 2007), then
53 they settle in nearshore areas (Fujita et al. 1988, Ohmi 2002, Arayama et al. 2002) and utilize there as nursery
54 areas (Hatanaka and Sekino 1962, Matsumiya et al. 1982, Hibino et al. 2002, Kinoshita 2002, Yamazaki 2002,
55 Fuji et al. 2010, Iwamoto et al. 2010, Nakane et al. 2010, Tamura et al. 2013, Fuji et al. 2016a). From the
56 juvenile stage, they utilize various coastal environments parallel as nurseries after early spring, e.g., seagrass
57 beds (Hatanaka and Sekino 1962, Kinoshita 2002), sandy beach (Fuji et al. 2010, Nakane et al. 2010), tidal flats
58 (Hibino et al. 2002, Tamura et al. 2013) and estuaries (Matsumiya et al. 1982, Yamazaki 2002, Fuji et al. 2010,
59 Iwamoto et al. 2010). Especially, estuaries have been considered as an important nursery for temperate seabass
60 because of its good prey environment (Fuji et al. 2016a) leading to high growth of juveniles (Fuji et al. 2011,
61 Fuji et al. 2014) and high contribution to adult population regardless of its small area relative to other coastal
62 areas (Fuji et al. 2016b). Success of migration into estuaries is one of the most important factors for juveniles to
63 achieve good survival (North and Houde, 2001). Estuaries, in which hydrodynamics are strongly affected by
64 river flow and tidal conditions, are characterized by the complexity of the hydrology (Kasai et al. 2010). It is
65 important to understand the mechanism of recruitment of juveniles into estuarine nursery areas to determine
66 effective conservation and stock management strategies.

67 Environmental conditions would control migration ecologies of juveniles, e.g., timing and distance of
68 juvenile migration, through both physical and biological ways. First, hydrological conditions affect the

69 movements of juveniles directly. Especially, juveniles should overcome the river flow regardless of their poor
70 swimming ability. Larvae of some species of fish including temperate seabass use tidal currents to overcome this
71 difficulty. They distribute in the surface or middle layers to migrate onshore and upstream with the onshore flood
72 tidal currents. They move to the bottom layer and reside there during the ebb tide to avoid offshore currents. This
73 mechanism is called “tidal selective transport” (Yamashita et al. 1996, Gibson 1997, Islam et al. 2007). However,
74 in microtidal estuaries, fishes cannot use this mechanism, so that they would use another way to migrate.
75 Saltwedge intrusion is another possible environmental factor which juveniles might use when they ascend the
76 microtidal estuaries, because water flows upstream in the saltwedge (Dyer 1973). This would be effective for
77 juveniles to avoid flowing out by the river current and achieve efficient ascending to upper estuaries. However,
78 few researchers have focused on the relationship between juvenile river ascending and saltwedge intrusions.

79 Second, many studies have reported that there are various endogenous factors for starting the migration
80 behavior of fishes (Boubée et al. 2001, Tsukamoto et al. 2009). There are mainly two distinct processes
81 controlling migration of fish: first, the juveniles undergo the physiological, morphological and behavioral changes
82 necessary to migrate, and second, the environmental triggers stimulate migration behaviors when endogenous
83 conditions have been completed (Solomon 1978, Tsukamoto et al. 2009). Temperature is one of the most
84 important factors for initiating migration behavior of juveniles by fulfilling these endogenous conditions (Uchida
85 et al. 1990, Benoît et al. 2000, Zydlewski et al. 2005, Jansen and Gislason 2011). In the case of smolts of salmonid
86 fishes, seasonal increases in day length and temperature are hypothesized to synchronize physiological and
87 behavioral changes necessary for successful migration to the sea (McCormick et al. 1998). Therefore, many
88 studies have described the relationship between temperature and the timing of migration in the field. The
89 cumulative temperature has been often used as the indicator of starting fish migration for several kinds of fish
90 (Zydlewski et al. 2005, Nakamura and Kasuya 2004). However, the endogenous processes stop below a certain
91 temperature, called “base temperature” (Kaeriyama 1989, Trudgill et al. 2005). The difference between observed
92 temperature and base temperature (effective temperature) is more meaningful to consider the effects of
93 temperature on the biological processes. Effective cumulative temperature thus should be used as the indicator of

94 the various biological processes (Kaeriyama 1989, Trudgill et al. 2005).

95 Hypothesis in this study is that juvenile temperate seabass uses the saltwedge intrusion for ascending the
96 microtidal estuaries. In addition, the relationship between effective cumulative temperature and timing of river
97 ascending was also estimated to confirm that temperature is also an important factor for deciding the timing of
98 river ascending.

99

100

101 **Materials and methods**

102

103 **Sampling field**

104

105 Observations and samplings were conducted along the lower reaches of the Yura River and adjacent coastal area
106 during the spring of 2009-2012 (Fig. 1). The Yura River flows into the Sea of Japan, where the tides are
107 generally small. As the typical tidal range in the estuary is <0.5 m (Kasai et al. 2010), we were able to neglect the
108 effect of tide on fish distributions and environmental conditions in this study. The river discharge of the Yura
109 River shows typical seasonal variations, namely, large in the winter and spring due to melting snow and small in
110 the summer and autumn (Kasai et al. 2010). In the winter, the whole estuary is filled with freshwater, and the
111 water is homogeneous. Seawater starts to intrude into the lower layer of the estuary from early spring onwards
112 and by the summer, the lower layer is occupied by sea water until approximately 15 km upstream from the river
113 mouth, leading to strong stratification.

114

115 **Field sampling**

116

117 Six stations were set up along the lower reaches of the river from the coastal surf zone to 15 km upstream
118 (St.1-St.6, Fig. 1). The distances from river mouth were 0.5, 3.0, 7.5, 11.0 and 15.0 km at St.2, St.3, St.4, St.5

119 and St.6, respectively. Another station (St.1) was set on the sand beach adjoining the river mouth (1.0 km from
120 the river mouth, Fig. 1).

121 In order to collect temperate seabass juveniles, a seine net (0.8 m×10 m, 1.0 mm mesh aperture at the cod
122 end) was towed along the bank or shoreline in March, April and May from 2009 to 2012. Three minute tows
123 were performed two times at each station. Sampling depth was 0.3 – 1.2 m at every station. The juveniles were
124 frozen in dry ice immediately after the collection. Care of the fish and all procedures were done following the
125 guidelines for the use of fishes in research of the Ichthyological Society of Japan (2003).

126 Conductivity data loggers (INFINITY-CT A7CT-USB, JFE ADVANTEC) were set on the bottom of the
127 river to monitor the change of bottom salinity with the saltwedge intrusion. The loggers were set at the stations 0,
128 6 and 11 km from the river mouth (Fig. 1). The loggers were set from February to May every year. However, in
129 2012 no logger was set at 0 km. The data logger at 6 km upstream was lost because of a flood event in May 2011.
130 Salinity was recorded every 10 minutes.

131 Stations were divided into three groups; coastal area (St.1 and St.2), lower estuary (St.3 and St.4) and upper
132 estuary (St.5 and St.6) for simplification. Standard length (SL: mm) was measured for every individual.

133

134 **Laboratory analysis**

135

136 Individuals for otolith analysis were haphazardly selected from each sampling station on 18 March and 15 April
137 2009, 28 April 2010, 18 May 2011 and 23 April 2012. Otoliths (lapillus) were removed from those samples,
138 embedded in epoxy resin on glass slides and polished with fine sandpaper until the core clearly appeared. Lapilli
139 were used in this study because they were subject to fewer sub-daily increments and peripheral primordia than
140 sagittal otoliths for seabass juveniles of ca. 20 to 30 mm SL (Fujita 2004, Suzuki et al. 2008, Islam et al. 2009).
141 Daily rings of otoliths were counted using a video monitor and an otolith reading system (ARP/W, Ratoc System
142 Engineering). Age of temperate seabass juvenile was estimated by adding 4 to the increment counts, as the first
143 daily increment is deposited at day 4 (the first feeding date) in the lapilli of this species (Suzuki et al. 2008).

144

145 **Environmental data**

146

147 Daily mean discharge data of the Yura River from March to May in 2009-2012 (measured in Fukuchiyama, 37
148 km upstream from the river mouth; Fig. 1b) were obtained from Ministry of Land, Infrastructure, Transport and
149 Tourism (<http://www1.river.go.jp/cgi-bin/SiteInfo.exe?ID=306091286605030>). As representative of the
150 temperature in the Tango Sea, daily temperature data in the Tango Sea at the depth of 12 m in Miyazu (Fig. 1c)
151 were obtained from Kyoto Prefectural Agriculture, Forestry and Fisheries Technology Center. Daily mean sea
152 water level data in the same period in the Maizuru port (Fig. 1c) were obtained from Japan Meteorological
153 Agency (<http://www.data.jma.go.jp/kaiyou/db/tide/suisan/suisan.php>).

154

155 **Data analysis**

156

157 The distance of saltwedge intrusion in the Yura River estuary was estimated from the daily sea level at Maizuru
158 and river discharge at Fukuchiyama using the equation from Kasai et al. (2010). The distance of saltwedge
159 intrusion was defined here as the distance from the river mouth to the tip of the saltwedge, where salinity was 5
160 in the bottom water (Kasai et al. 2010). The distance from river mouth to the most upstream station in which
161 juveniles were collected is defined as juvenile river ascending distance. These two distances, saltwedge distance
162 and juvenile ascending distance, were compared.

163 SL - daily age linear relationships were determined for every year. The ages of all individuals in each year
164 were estimated by using these relationships and SL data. Individuals with the SL that is out of the age range of
165 samples for otolith analysis were eliminated from this estimation. In total, 6.3 % (169 individuals) were
166 eliminated from age estimations, as their ages were uncertain. Hatch dates were estimated from estimated age
167 and collected date for each individual. Individuals were categorized into some cohorts with 10 days duration.
168 The cohorts including more than 5 individuals were selected for further analysis.

169 River ascending index on i th sampling day (A_i) were defined for each cohort as follows;

$$170 \quad A_i = N_i - N_{i-1}, \quad (1)$$

171 where N_i is the total number of individuals collected in the lower and upper estuary on the i th sampling day.

172 A_i was set as zero when N_i was smaller than N_{i-1} . $\%A_i$ was then calculated as follows;

$$173 \quad \%A_i = \frac{A_i}{\sum A_i}, \quad (2)$$

174 where $\sum A_i$ means sum of A_i values for all sampling days of the year. Then $\sum \%A_i$ was resulting in the

175 equation

$$176 \quad \sum \%A_i = \sum_{j=1}^i \%A_j. \quad (3)$$

177 The law of effective cumulative temperature is described as follows (Kaeriyama 1989, Trudgill et al. 2005)

$$178 \quad k = D(T - t), \quad (4)$$

179 where k ($^{\circ}\text{C}$ -days) is an effective cumulative temperature. D (days) is period that a biological process takes to
180 complete, T ($^{\circ}\text{C}$) is mean temperature during a biological process and t ($^{\circ}\text{C}$) is designated as a base temperature.

181 Base temperature is considered as the lower limit below which the biological process will cease (Trudgill et al.

182 2005). In this study, the juvenile ascent is considered as a biological process. Here, D is the period that each

183 cohort takes to start ascending the river (equal to the mean daily age of each cohort at the day of ascending the

184 river) and T is mean temperature that juveniles experienced in the sea during the period between mean hatch

185 date of the cohort and the day of ascending the river. The day of ascending the river is defined by following two

186 ways; first days that individuals started to be collected in the lower or upper estuary (first ascending day) and

187 main ascending days that most of individuals ascend, which is defined as the day that $\%A_i$ exceeded 50. Both

188 days were determined for each cohort. Parameters k and t were estimated by a linearizing transformation for

189 the variable D resulting in the equation

$$190 \quad \frac{1}{D} = -\frac{t}{k} + \frac{T}{k}. \quad (5)$$

191 t and k are constants and estimated from the linear regression of T and $1/D$. t and k were estimated for

192 both first river ascending days and main river ascending days. Cumulative $\%A_i$ ($\sum \%A_i$) and effective

193 cumulative temperatures were compared to detect the relationship between river ascending behavior and

194 temperature.

195

196

197 **Results**

198

199 **Dynamics of the saltwedge intrusion and juvenile river ascending**

200

201 The fluctuation patterns of river discharge in spring were different among the four years (Fig. 2). River discharge
202 in 2009 was low throughout spring season except for a flood event in March. In 2010, there were many flood
203 events from March to the end of April, and subsequently river flow decreased in May. The river discharge was
204 low until April and then two heavy floods (over 1000 m³/s) occurred in the middle and late May 2011. In 2012,
205 river flow was high until mid-April, but low after late April.

206 Salinity in the bottom layer changed according to the fluctuation of the river discharge (Fig. 3). In 2009,
207 bottom salinity started to increase at 6 km upstream since the beginning of March. Then the saltwedge reached
208 11 km upstream from the beginning of April which is in good agreement with low discharge after April. In 2010,
209 the saltwedge intruded into the river up to 6 km upstream from the end of April when the river discharge
210 decreased. The saltwedge then reached 11 km upstream in the beginning of May. In 2011, salinity around the
211 river mouth increased from April, and then the saltwedge reached 11 km upstream in the middle of April and
212 mid-May, followed by being flushed out by the large floods. Bottom salinity at 6 km upstream began to rise from
213 the beginning of April 2012. Then the saltwedge reached to 11 km upstream in the middle of April.

214 Timings of juvenile movement from the coastal area to the lower estuary and the lower estuary to the upper
215 estuary corresponded to the saltwedge movements (Fig. 3). For example, in 2009, juvenile distributions were
216 restricted in the coastal area and the lower estuary during March and beginning of April, when the saltwedge
217 intruded until 6 km upstream. Juveniles then reached the upper estuary from mid-April, corresponding to the rise
218 of bottom salinity at 11 km upstream (Fig. 3). These correspondences were observed in all years. Comparison

219 between estimated saltwedge intrusion distance and juvenile ascending distance showed juveniles rarely
220 ascended further than the saltwedge intrusion (Fig. 4). Juveniles went beyond the saltwedge only 15 April 2009
221 and 18 May 2011.

222

223 **Temperature and timings of river ascending of juveniles**

224

225 Temperature in Miyazu was generally high in 2009 and low in 2010 and 2011 (Fig. 5). Temperature decreased
226 from December to March and lowest temperature was recorded in March in every year. Then temperature started
227 to increase from the end of March.

228 In total, ages of 204 individuals with the size range from 13.7 mm to 28.3 mm SL were determined and then
229 Age-SL relationships in each year were estimated (Table 1). Using these relationships, SL data were converted to
230 daily age data. Hatch date distributed mainly from the mid-January to mid-February (Fig. 6). The peak was at the
231 end of January in 2009, 2010 and 2012, while mid-February in 2011. Samples were categorized into some
232 cohorts (Fig. 6). % A_i change with time comprised mainly of two phases (Fig. 7); low intensity ascent (% A_i were
233 mostly lower than 30%) followed by mass ascent (% $A_i > 50$ %). Different cohorts showed different timing of
234 surge; earlier cohorts ascended earlier. The first day of ascending among cohorts ranged from 9 March (cohort A
235 in 2009) to 18 May (cohort G in 2011). The day of main river ascending was considerably different ranging from
236 10 April (2012) to 18 May (2011). Mean temperature they experienced until the first ascending day (T) ranged
237 from 11.0 to 12.7 °C (Fig. 8a), showing a significant correlation with $1/D$ (Pearson's correlation coefficient: R^2
238 = 0.39, $P \leq 0.05$), while no significant relationship was obtained for the main river ascending day ($P > 0.05$, Fig.
239 8b). Base temperature (t) and effective cumulative temperature (k) were estimated as 5.0 °C and 514.1 °C-days
240 for the first ascending day. Temperature on the first day of ascending was not a specific level or value, but varied
241 ranging from 11.7 to 16.1 °C (Fig. 9a). However, all cohorts in all four years showed a similar pattern of
242 cumulative A_i trajectories against effective cumulative temperature (Fig. 9b). Most of the cohorts started to
243 ascend the river at the ca. 500 °C-days. Many cohorts that did not attain the effective cumulative temperature

244 distributed only in the coastal area, even though the saltwedge had already intruded (Fig. 10).

245

246 **Discussion**

247

248 Juveniles changed their distribution in the Yura River depending on the change of saltwedge intruding distance
249 (Fig. 3). Distances that juveniles ascended the river were within the estimated distances of saltwedge intrusion
250 except for 15 April 2009 and 18 May 2011 (Fig. 4). Although estimated distance of the saltwedge intrusion on 15
251 April 2009 was 9.3 km, the conductivity logger observed saltwater at 11 km upstream which is the most
252 upstream station juveniles were collected on that date (Fig. 3). This indicates that juvenile distribution on this
253 date was still below the distance of the saltwedge intrusion. On the other hand, both estimated distance of
254 saltwedge intrusion and bottom conductivity logger indicated that the saltwedge remained around 11 km
255 upstream, while juveniles went further on 18 May 2011. Only larger individuals (> 23 mm SL) reached to 15 km
256 upstream (St. 6), while smaller ones (< 23 mm SL) remained at 11 km upstream (St. 5) on 18 May 2011. This
257 would mean that only larger juveniles have enough osmoregulatory and swimming ability to ascend the river
258 against the freshwater flow. Given the information that most of juveniles ascend the river with the size smaller
259 than 23 mm SL (Fuji et al. 2011), early juvenile temperate seabass utilized the saltwedge intrusion to ascend the
260 Yura River estuary. In the Chikugo River estuary, which is characterized by its large tidal amplitude, juveniles of
261 temperate seabass use tidal selective transport to ascend the river (Islam et al. 2007). Not only temperate seabass
262 but also many fish species utilize the tidal currents for migration in their early life stage because their swimming
263 abilities are not enough to move against strong water currents (Yamashita et al. 1996, Gibson 1997, Islam et al.
264 2007). However, in the Yura River estuary, there is no strong tidal upstream current because of small tidal
265 amplitude (Kasai et al. 2010). This means that juveniles cannot use the tidal selective transport in this area. The
266 temperate seabass juveniles are small when they ascend the river (ca. 20 mm SL) (Fuji et al. 2011). Generally
267 speaking, swimming speed of fish is ca. 10 times of their body length and small juveniles have little ability to
268 swim (Tsukamoto and Kajihara, 1973). For example, juvenile red seabream *Pagrus major* at the size of 20 mm

269 SL can swim at 0.18 m/s at a maximum (Yano and Ogawa 1981). On the other hand, surface water at the Yura
270 River mouth flows downstream at the speed of 0.22 m/s in summer, the lowest river discharge season in a year
271 (Yamazaki et al. 2005). It is considered that this current speed even increases in winter and spring when the river
272 discharge is higher than summer because of snow melting (Kasai et al. 2010). This means that it is difficult for
273 juvenile seabass to ascend the river against the surface water current. In addition, osmoregulatory ability of small
274 juveniles is still not completed and drastic change of salinity of ambient water would be lethal for seabass
275 juveniles (Hirai 2002). Around the Yura River mouth the salinity of the surface water in spring drastically
276 changes from ca. 30 to almost 0 within a small spatial range (ca. 1 km) (Kasai et al. 2010). On the other hand,
277 there is a stable broad brackish layer between the saltwedge and the surface layer in the Yura River estuary
278 (Kasai et al. 2010) in which juveniles can physiologically adjust to lower salinity. In addition, water flows
279 upstream in the bottom layer when the saltwedge intrudes (Dyer 1973). Therefore, it is efficient for juveniles to
280 use the saltwedge intrusion to ascend the microtidal estuary.

281 The timing of the saltwedge intrusion and that of juvenile river ascending sometimes were mismatched;
282 sometimes no juveniles were found in the river even though the saltwedge intruded into the river, especially
283 during April in 2011 (Fig. 4). We also observed that many cohorts with the insufficient cumulative temperature
284 (< ca. 500 °C-days) resided in the coastal area regardless of the saltwedge intrusion (Fig. 10). This means that the
285 saltwedge intrusion is one of the necessary conditions, but not a sufficient condition for juveniles to ascend the
286 river. Saltwedge intrusion would be like opening a gate: juveniles can enter the estuary only when the gate opens.
287 However, it does not mean that juveniles always ascend the river when the saltwedge intrudes. This study
288 suggests that temperature would have a decisive influence on the timing of the river ascending.

289 Some previous papers reported that there are temperature thresholds for initiating the fish migration
290 (Kusuda 1963, Solomon 1978). On the other hand, cumulative temperature is known to be a good index for
291 predicting timings of migration for some fishes (Bohlin et al. 1993, Nakamura and Kasuya 2004, Zydlewski et al.
292 2005, Hoffman et al. 2008). This study advocates the latter studies (Fig. 9). Former studies did not consider the
293 effects of hatch dates and only focused on the first ascending day in a year. The present study showed many

294 cohorts ascended the river in various timings (Fig. 7). This means that the temperatures when they started
295 ascending are different among the cohorts and there should be no threshold of temperature initiating migration
296 behavior (Fig. 9). The effective cumulative temperature provides a major of “duration” required for the
297 completion of the biological process (Trudgill et al. 2005). Therefore, there could be some biological processes
298 which should be completed before starting the river ascending. The body development which is relating to the
299 river ascending, e.g., ability developments of swimming and osmoregulation, would be biological processes to
300 be completed. Higher temperature often leads to short periods of metamorphosis (body development) in larvae of
301 many marine fish species (Benoît et al. 2000). Completion of metamorphosis of seabass juveniles corresponds to
302 the complement of swimming ability and osmoregulation, which are necessary for diadromous migrations (Hirai
303 2002). This means that larvae under higher temperatures can complete the preparation for diadromous migrations
304 in younger age. This enables them to ascend the river at younger ages (Fig. 8a). Base temperature (t) estimated
305 in this study (5.0 °C) means the temperature at which body development of larval temperate seabass cease.
306 Makino et al. (2003) reported that no eggs of temperate seabass hatched out at 5 °C.

307 On the other hand, the effective cumulative temperature was not a good indicator for the main river
308 ascending days (Fig. 9). There should be other factors which induce the mass river ascending of juveniles.
309 Tsukamoto et al. (2009) considered that fish start to migrate by receiving a trigger from particular endogenous or
310 exogenous factors after filling necessary conditions, e.g., age or body size. After filling the necessary conditions,
311 particular stimulations would induce the migration behavior of juveniles. Rainfall and the following high
312 turbidity are possible triggers for starting migration for some fishes (Boubée et al. 2001, Iwata et al. 2003). In the
313 case of catadromous ayu, stimuli of a waterfall is the important factor to induce the river ascending behavior
314 (Uchida et al. 1990). Being exposed to river plume in the coastal area might be one of the potential triggers for
315 juvenile temperate seabass to start river ascending behavior, because juvenile temperate seabass starts to change
316 the structure of gills to adjust to lower salinity water after they experienced lower salinity water (Hirai et al.
317 1999). Main river ascending of most cohorts occurred after flood events (Figs. 2 and 7).

318 This study suggests that the mechanism of river ascending of juvenile temperate seabass was estimated as

319 follows; juveniles start to ascend the river after at least two conditions were filled; body development, which is
320 indexed by effective cumulative temperature of 514.1 °C-days, and saltwedge intrusion. Recruitment to riverine
321 nurseries is important for juvenile temperate seabass because of its good prey environment (Fuji et al. 2016a),
322 which leads to high growth rates (Fuji et al. 2014) and high contribution to its adult population (Fuji et al. 2016b).
323 Therefore, both temperature and saltwedge dynamics could be crucial factors for population dynamics by
324 restricting the river ascending. In the four years in this study, temperature was the main restricting factor of
325 starting the river ascending (Fig. 10), because the saltwedge almost resided in the river during sampling seasons.
326 Low temperature in winter could disturb the river ascending and extend the period for stay in the coastal area,
327 where higher mortality would be caused by many predators. On the other hand, high river discharge during
328 winter-spring season might also restrict the utilization of riverine nursery area. For example, Shoji et al. (2006)
329 considered that high river flow had the potential to decrease the probability of immigration of juvenile seabass
330 into the Chikugo River estuary by increasing juvenile seaward dispersion. Shoji and Tanaka (2006) also argued
331 the reason for ascending would lead to lower mortality, because there are more predators in the high salinity
332 environment, e.g. jellyfishes and arrow-worms. Annual variation of the saltwedge intrusion could affect the
333 recruitment of temperate seabass in the rivers into Tango Sea or the generality to other rivers in this area. Further
334 study is necessary to confirm this possibility.

335

336 **Acknowledgements**

337 We would like to express our sincere gratitude to Dr. Masahiro Ueno for his creative comments and help for
338 samplings. This study was partly supported by the Coastal Ecosystem Complex Project of the Ocean Resource
339 Use Promotion Technology Development Program, MEXT of Japan.
