Abstract: The aim of this study is to clarify the effects of 3-week work-matched high-intensity intermittent cycling training (HIICT) with different cadences on the VO$_{2\text{max}}$ of university athletes. Eighteen university athletes performed HIICT with either 60 rpm ($n=9$) or 120 rpm ($n=9$). The HIICT consisted of eight sets of 20 s exercise with a 10 s passive rest between each set. The initial training intensity was set at 135% of VO$_{2\text{max}}$ and was decreased by 5% every two sets. Athletes in both groups performed nine sessions of HIICT during a 3-week period. The total workload and achievement rate of the workload calculated before experiments in each group were used for analysis. VO$_{2\text{max}}$ was measured pre- and post-training. After 3 weeks of training, no significant differences in the total workload and the achievement rate of the workload were found between the two groups. VO$_{2\text{max}}$ similarly increased in both groups from pre- to post-training ($p=0.016$), with no significant differences between the groups ($p=0.680$). These results suggest that cadence during HIICT is not a training variable affecting the effect of VO$_{2\text{max}}$.

Keywords: aerobic capacity; graded-exercise test; total workload

1. Introduction

High-intensity intermittent (or interval) training (HIIT) is considered a time-efficient exercise strategy, due to its superior effect toward improving VO$_{2\text{max}}$ in less time than low- or moderate-intensity continuous exercise [1,2]. In addition, HIIT can increase VO$_{2\text{max}}$ in a short period (2–4 weeks) [3–9]. Since the total available time for training is often limited for athletes, it is important to determine the more effective HIIT methodology for increasing VO$_{2\text{max}}$ in a short period.

HIIT with the use of a cycle ergometer is considered a safe method of training, and cadence may be a training variable that affects the chronic effect of VO$_{2\text{max}}$. In previous studies, various training modes, such as cycling, running, aquatic treadmill running, jump rope, swimming, and kettlebell training, have been attempted [10]. Results showed that the stress on the anterior cruciate ligament was lower during cycling exercise [11,12]. In addition, cycling exercise was found to be associated with fewer eccentric contraction phases, which cause muscle damage, when compared to running [13]. Thus, HIIT by using a cycle ergometer can increase VO$_{2\text{max}}$ more safely. The cadence used during work-matched cycling training may be a training variable that affects the chronic effect of VO$_{2\text{max}}$ under relative intensity (e.g., %VO$_{2\text{max}}$) and the length of time applied to the exercise-matched
condition. The workload during cycling exercise is a product of load (kp) and cadence (rpm). Therefore, high-intensity intermittent cycling training (HIICT) can be performed either with high load/low cadence or with low load/high cadence under the workload, relative intensity (e.g., %VO$_{2\text{max}}$), and exercise time-matched conditions [14]. Many previous studies reported that oxygen uptake (VO$_2$) during work-matched cycling exercise increases more significantly in high-cadence cycling than in low-cadence cycling (35–110 rpm) due to the elevated internal workload of active muscles [15–20]. Thus, work-matched cycling exercise with a high cadence may have a higher actual intensity than cycling exercise with a low cadence, even though the relative intensity (e.g., %VO$_{2\text{max}}$) is equal. Matsuo et al. reported that high-intensity interval training improves VO$_{2\text{max}}$ more significantly than moderate-intensity training due to an increase in left ventricular mass and stroke volume [21]. Therefore, it can be speculated that HIICT with a high cadence can improve VO$_{2\text{max}}$ more significantly than HIICT with a low cadence. In contrast, Paton et al. reported that high-intensity interval training with a low cadence significantly improved VO$_{2\text{max}}$ compared to that of a high cadence in male cyclists [22]. However, workload was not matched in this study. Since the workload affects the chronic effect of VO$_{2\text{max}}$ [23], the effect of the difference in cadence on VO$_{2\text{max}}$ should be examined under work-matched conditions.

The aim of this study, therefore, was to examine whether 3-week work-matched HIICT with a high cadence (120 rpm) can significantly improve VO$_{2\text{max}}$ compared to HIICT with a low cadence (60 rpm) in university athletes.

2. Materials and Methods

2.1. Experimental Design

Participants were assigned to one of two groups according to their workload of HIICT, calculated based on pre-training VO$_{2\text{max}}$. One group of participants performed HIICT with a low cadence of 60 rpm ($n = 9$, age: 20.1 ± 0.8 years, height: 174.6 ± 4.8 cm, body weight: 65.4 ± 3.9 kg) and the other group of participants performed HIICT with a high cadence of 120 rpm ($n = 9$, age: 20.0 ± 1.0 years, height: 173.2 ± 5.3 cm, body weight: 64.4 ± 6.3 kg). HIICT was performed by both groups in nine sessions during a 3-week period and at least twice per week in order not to bias the number of sessions per week. In both groups, training load was increased by 2.5% after every three sessions. All training sessions were supervised by investigators with expert knowledge of HIICT. VO$_{2\text{max}}$ measurement during the graded-exercise test using a cycle ergometer was carried out pre- and post-training. All measurements for each participant were performed at approximately the same time of day (±2.5 h) to take into consideration the circadian rhythm.

2.2. Participants

A total of 21 Japanese male university athletes were initially recruited. However, three participants could not complete the training due to injuries unrelated to the experiment. Thus, data from 18 participants were used for further analysis. All participants practiced exercise at least twice per week and belonged to the university volleyball ($n = 8$), soccer ($n = 3$), soft tennis ($n = 3$), ultimate ($n = 2$), badminton ($n = 1$), and sailing ($n = 1$) teams. Participants did not habitually perform any physical training, except for practice for their respective sports; furthermore, no participants had performed resistance training for the lower body more than two times per week during the previous 6 months or performed any cycling training for a competitive race. All participants were informed about the potential risks of experiments and provided written consent prior to participation. This study was approved by the Ethics Committee of Faculty of Education, Hokkaido University (approval number: 17–24).
2.3. VO\textsubscript{2max}

The graded-exercise test using a cycle ergometer (Powermax-VII, Combi Wellness, Tokyo, Japan) was performed to determine VO\textsubscript{2max} and relative intensity of the HIICT. The test was initiated at 60 W, followed by 30 W increases every 3 min until each participant was unable to maintain a cadence of 60 rpm. The cadence during the test was controlled by a metronome and was displayed on a screen. During the test, VO\textsubscript{2} was measured every 10 s using mixing chamber methods with a respiratory gas analyzer (VO2000, S&ME Co. Ltd., Tokyo, Japan) and the peak value was defined as VO\textsubscript{2max} \cite{24–26}.

2.4. High-Intensity Intermittent Cycling Training

In all training sessions, the HIICT was performed by using a cycle ergometer (Powermax-VII, Combi Wellness, Tokyo, Japan) following a warm-up at 90 W for 10 min and a rest period of 3 min. The initial training intensity of the HIICT was set at 135% of VO\textsubscript{2max} and was decreased by 5% every two sets. HIICT consisted of eight sets of 20 s pedaling, with a 10 s passive rest between each set. This protocol was conducted according to the results of our pilot study that was, in turn, based on previous studies \cite{3,27,28}. Participants were instructed to maintain a cadence of either 60 rpm or 120 rpm, which was controlled by the value displayed on the screen and a metronome during each session. After the HIICT, participants performed a cool down at 90 W for 5 min in all training sessions. The total workload and achievement rate of the workload calculated before experiments involving each group were used for analysis. The cadence was decided to be insufficient if the workload during the 3-week period did not reach 90% of the workload calculated prior to the experiments; these data were excluded from the analysis. The average value of the absolute load of the HIICT during the training period is shown in Table 1.

VO\textsubscript{2max} values are mean ± SD. 60 rpm, High-intensity intermittent cycling training with 60 rpm; 120 rpm, High-intensity intermittent cycling training with 120 rpm.

2.5. Statistical Analyses

All data are presented as means and standard deviations (SD). Total workload, achievement rate, baseline VO\textsubscript{2max} levels, and percent change of VO\textsubscript{2max} in both study groups were analyzed using the unpaired \textit{t}-test. Moreover, the changes in VO\textsubscript{2max} and body weight from pre- to post-training were analyzed by two-way (group × time) mixed-design analysis of variance (ANOVA; between-participant factor: group, within-participant factor: time). A post hoc analysis was performed using the Bonferroni test. The statistical significance level was set at \(p < 0.05\). As indices of the effect size, Cohen’s d (for unpaired \textit{t}-test and post hoc comparisons) and partial \(\eta^2\) (for ANOVA) were also calculated. SPSS Statistics (version 24.0 for Windows, SPSS Inc., Chicago, IL, USA) was used for data analysis.

3. Results

All 18 participants who completed the nine training sessions exceeded the 90% achievement rate of the workload calculated prior to the experiments. No significant differences in the baseline VO\textsubscript{2max} levels were found between the groups (\(p = 0.967\), Cohen’s d = 0.020, 60 rpm: 59.2 ± 3.9 mL/kg/min, 120 rpm: 59.3 ± 5.5 mL/kg/min). The total workload and achievement rate of the workload calculated...
before the experiments for each group are shown in Table 2. No significant differences in the total workload and achievement rate of the workload were found between the groups.

Values are mean ± SD. 60 rpm, High-intensity intermittent cycling training with 60 rpm; 120 rpm, High-intensity intermittent cycling training with 120 rpm.

The main effects of time and interaction were not observed in body weight (main effect of time: \( p = 0.821 \), partial \( \eta^2 = 0.03 \), interaction: \( p = 0.821 \), partial \( \eta^2 = 0.03 \)), 60 rpm pre-training: 65.4 ± 3.9 kg, 60 rpm post-training: 65.4 ± 3.8 kg, 120 rpm pre-training: 64.4 ± 6.3 kg, 120 rpm post-training: 64.3 ± 5.9 kg. Results in terms of change in VO\(_{2}\max\) from pre- to post-training between groups are shown in Figure 1. The main effect of time was observed in VO\(_{2}\max\) (\( p = 0.016 \), partial \( \eta^2 = 0.031 \)). However, no interaction was observed (\( p = 0.680 \), partial \( \eta^2 = 0.011 \)). No significant difference was detected in the relative change of VO\(_{2}\max\) (\( p = 0.675 \), Cohen’s d = 0.201, 60 rpm: 4.3 ± 6.2%, 120 rpm: 3.2 ± 5.5%). The average values of VO\(_{2}\max\) were as follows: 60 rpm pre-training: 59.2 ± 3.9 mL/kg/min, 60 rpm post-training: 61.7 ± 4.4 mL/kg/min, and 120 rpm pre-training: 59.3 ± 5.5 mL/kg/min, 120 rpm post-training: 61.1 ± 6.1 mL/kg/min.

![Figure 1](image-url)  
Figure 1. Change of VO\(_{2}\max\) from pre- to post-training in 60 rpm and 120 rpm. Each line represents the change for an individual participant. Bars are the average value for all participants. Error bars are the standard deviation. * \( p < 0.05 \) vs pre-training in each group. 60 rpm: high-intensity intermittent cycling training with 60 rpm; 120 rpm: high-intensity intermittent cycling training with 120 rpm.

4. Discussion

To the best of the author’s knowledge, this is the first study to examine whether 3-week work-matched HIICT with a high cadence (120 rpm) significantly improves VO\(_{2}\max\) in university athletes, compared to a low cadence (60 rpm). As a result of a 3-week training period, VO\(_{2}\max\) increased similarly for 60 rpm and 120 rpm from pre- to post-training. These results were contrary to our hypothesis.

There are two possibilities explaining why there was no significant difference in the effect on VO\(_{2}\max\) between 60 rpm and 120 rpm in this study. First, the VO\(_{2}\) response during the HIICT in this study may be similar for 60 rpm and 120 rpm, unlike the different responses seen in previous studies [15–20]. In many previous studies, VO\(_{2}\) was higher during work-matched cycling exercise with a high cadence than a low cadence [15–20]. However, submaximal exercise intensity was used in these studies, while a much higher supramaximal intensity was used in this study. Recruitment of type II fiber has been shown to be increased at a low cadence compared to a high cadence during
submaximal cycling [29,30], and type II fiber has higher ATP consumption than type I fiber [31]. In this study, VO$_2$ responses might be similar between 60 rpm and 120 rpm due to the recruitment of more intense type II fibers than in previous studies by using supramaximal intensity. Future studies should investigate in detail the acute VO$_2$ response during work-matched HIICIT with different cadences.

The second possibility is that workload, rather than exercise intensity, affects VO$_{2\text{max}}$. In this study, if VO$_2$ during HIICIT with a high cadence was higher than with a low cadence like in many previous studies, HIICIT with a high cadence was higher in actual intensity compared to that with a low cadence, even though their relative intensity (e.g., %VO$_{2\text{max}}$) were the same. Matsuo et al. reported that high-intensity training improves VO$_{2\text{max}}$ more significantly than moderate-intensity training due to increased left ventricular mass and stroke volume [21]. On the other hand, Scribbans et al. [32] reported in their meta-analysis that increasing exercise intensity above 60% VO$_{2\text{max}}$ does not provide additional increases in VO$_{2\text{max}}$. In addition, Granata et al. [23] reported that VO$_{2\text{max}}$ can be changed by manipulating the total workload, not the relative intensity. Therefore, the similar chronic effect on VO$_{2\text{max}}$ in this study might be related to the equal workload in both groups.

In this study, the subjects had relatively high initial VO$_{2\text{max}}$ levels (60 rpm: 59.2 ± 3.9 mL/kg/min, 120 rpm: 59.3 ± 5.5 mL/kg/min) as compared to previous studies, in which the increase in VO$_{2\text{max}}$ was observed following a short training period (32.8–57.3 mL/kg/min) [3–9]. Nevertheless, VO$_{2\text{max}}$ significantly increased in both groups after the 3-week training period. This implies that, for regularly trained athletes, the 3-week HIICIT protocol used in this study appears to be an effective method to improve VO$_{2\text{max}}$ in the short term, regardless of cadences used during the HIICIT.

5. Conclusions

We examined whether 3-week work-matched HIICIT with a high cadence (120 rpm) significantly improves VO$_{2\text{max}}$ in university athletes compared to HIICIT with a low cadence (60 rpm). Following a 3-week training period, contrary to our hypothesis, VO$_{2\text{max}}$ increased similarly in groups using a cadence of 60 rpm or 120 rpm. These results suggest that cadence during 3-week work-matched HIICIT is not training variable affecting the short-term effect of VO$_{2\text{max}}$ in university athletes.
