## 学位論文内容の要約

博士の専攻分野の名称 博士（工学） 氏名 ウアガセーム ガサマー

### 学位論文題名

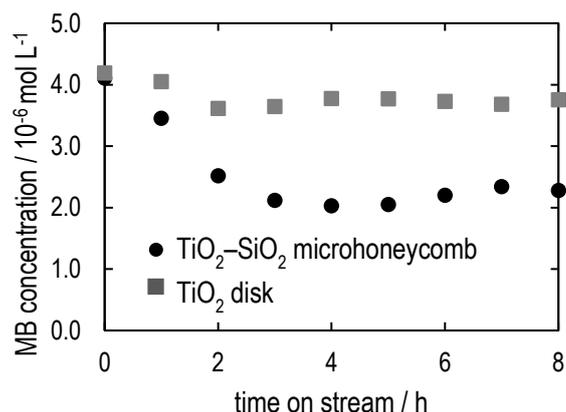

#### Development of Monoliths with Introduced Straight Microchannels for Applications in Continuous Wastewater Treatment

(直状マイクロ流路を導入したモノリス体の開発と連続式廃水処理への応用)

Wastewater from many industries is contaminated with soluble aromatics. Due to their high impacts to health and the environment even at a ppm-level concentration, strict standards and regulations regarding their concentration in wastewater effluents are applied worldwide. Among the treatment techniques for the water soluble aromatics, adsorption by carbon materials and heterogeneous photocatalysis are the two techniques widely studied. Along with the development of new adsorbents and photocatalysts with improved properties, continuing research on how to integrate them into a fixed bed is required to efficiently use them in continuous operations. Structured adsorbents and catalysts potentially overcome mass transfer limitations often encountered in conventional packed beds, while enabling high flow rate and minimal pressure drop. In this work, the use of porous monoliths with introduced straight microchannels and thin channel walls were suggested to overcome mass transfer limitations and further increase the contact area in wastewater treatment systems. The thin walls of the monolith would facilitate rapid mass transfer, and the straight microchannels would minimize the pressure drop when fluid flow through the monoliths. The synthesis methods, and the applications of the monoliths were discussed to show their potentials to be used for continuous treatment of soluble aromatics in wastewater.

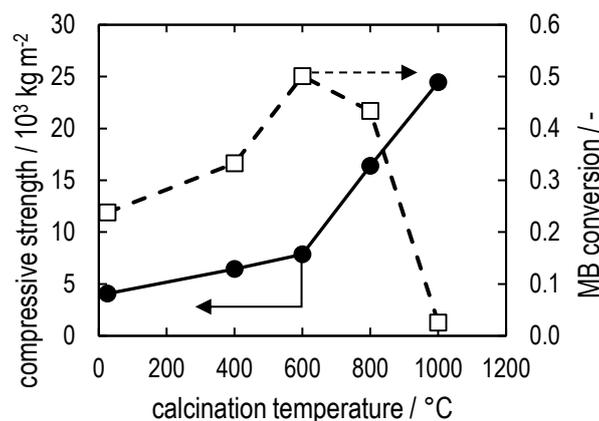

Part 1 (Chapter 2 and 3) describes the use of  $\text{TiO}_2\text{-SiO}_2$  monolithic microhoneycombs synthesized by the ice templating method for photocatalytic treatment of wastewater.

In Chapter 2,  $\text{TiO}_2\text{-SiO}_2$  microhoneycombs were synthesized using an inexpensive sodium silicate solution as a precursor for  $\text{SiO}_2$ , which is similar to the production of commercial silica gels. The use of reactive alkoxides of Ti could be avoided by using a commercial  $\text{TiO}_2$  sol instead. Monolithic microhoneycombs with 25 mol%  $\text{TiO}_2$  were successfully synthesized. The straight microchannels introduced by the ice templating method could minimize the pressure drop across the bed to less than a hundredth of that of beds packed with particles having the same diffusion path length. The samples also have high BET surface area of over  $500 \text{ m}^2 \text{ g}^{-1}$ , which could facilitate both radiative transport and adsorption of the substrate. This leads to improved photocatalytic activities compared with disk-type  $\text{TiO}_2$  photocatalysts having lower surface area, both in batch and continuous flow systems (data for continuous flow systems shown in Fig. 1). In addition, the effect of calcination temperature to photocatalytic activity was studied. Although  $\text{TiO}_2$  could retain its anatase phase even after calcination at  $1000^\circ\text{C}$ , the decrease in specific surface area led to the decrease in photocatalytic activity. The results emphasize an importance of photocatalysts with high specific surface area, which the synthesis could be realized by the ice templating method.

**Fig. 1** Photocatalytic activity of an uncalcined TiO<sub>2</sub>-SiO<sub>2</sub> microhoneycombs and TiO<sub>2</sub> disk having the same total amount of TiO<sub>2</sub> in the decolorization of MB in continuous flow systems (feed concentration: 4  $\mu\text{mol L}^{-1}$ , light intensity: 10 W m<sup>-2</sup>, superficial velocity: 0.23 cm min<sup>-1</sup>). Conversions of MB were 0.44 and 0.10 for TiO<sub>2</sub>-SiO<sub>2</sub> microhoneycombs and TiO<sub>2</sub> disk, respectively.

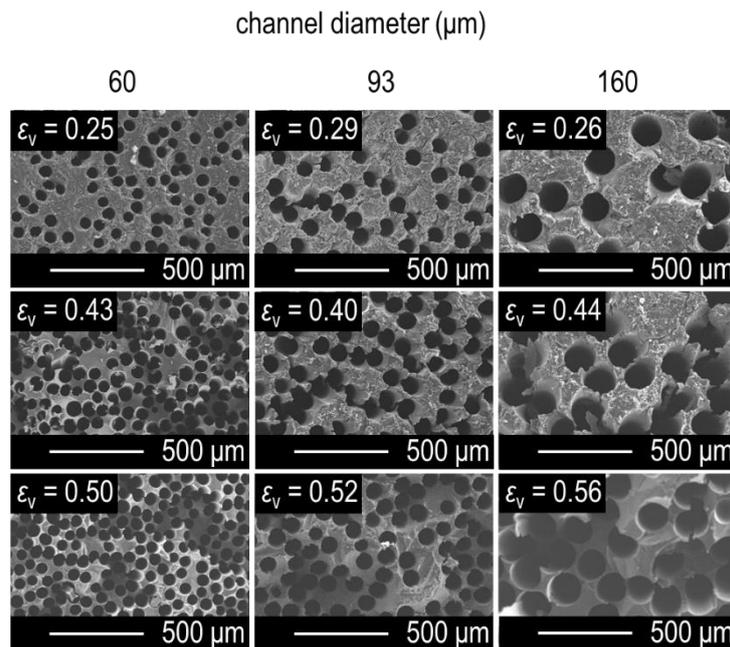

In Chapter 3, the synthesis method of TiO<sub>2</sub>-SiO<sub>2</sub> microhoneycomb photocatalysts was further improved by using two sources of TiO<sub>2</sub> sols stabilized at different pH, so that the morphology of the samples can be controlled independently from TiO<sub>2</sub> content. This synthesis method resulted in uniform distribution of TiO<sub>2</sub> inside SiO<sub>2</sub> matrix, so samples having 10 mol% TiO<sub>2</sub> synthesized by the improved method could show similar photocatalytic activity compared with the 25 mol% TiO<sub>2</sub> samples synthesized by the method introduced in Chapter 2. The effect of calcination temperature was studied again in this chapter. It was found that samples calcined at 600–800 °C had improved compressive strength and photocatalytic activity, while retaining the anatase phase of TiO<sub>2</sub> and high BET surface area of over 500 m<sup>2</sup> g<sup>-1</sup> (Fig. 2). It was also found that microhoneycomb morphology was not only effective in minimizing the pressure drop across the system, but also in uniform distribution of the feed flow, compared with systems with packed bed of particles having the same diffusion path length. The results further illustrates the potentials of microhoneycomb-shaped photocatalysts to be used to fulfill various process demands.

**Fig. 2** Compressive strength and conversion of MB, tested using TiO<sub>2</sub>-SiO<sub>2</sub> microhoneycombs calcined at various temperatures (feed concentration: 4  $\mu\text{mol L}^{-1}$ , light intensity: 10 W m<sup>-2</sup>, superficial velocity: 0.76 cm min<sup>-1</sup>, data points for uncalcined sample are shown at 25 °C).

One of the limitations of larger honeycomb photoreactors (mm-order channels) is that the light intensity rapidly decrease along the length of the monolith, and the optimal aspect ratio of the monoliths has to be determined. The design guidelines of monolithic adsorbents also stated that it is crucial to be able to make monoliths having optimal channel size and wall thickness. Therefore, the synthesis methods of monoliths with straight microchannels which allow independent control of channel size and wall thickness are preferred. However, it is difficult to do so in the ice templating method. Therefore, in Part 2 (Chapter 4 and 5), a new synthesis method of monoliths with introduced microchannels, which allows independent control of channel size and wall thickness, was developed.

In Chapter 4, a new synthesis method to synthesize monoliths with introduced straight microchannels was developed. The “fiber templating method” used polyester fibers, which decompose at high temperatures, leaving only a trace of them behind, to introduce the microchannels to the monoliths. Carbon gels synthesized by the polycondensation of resorcinol and formaldehyde were selected due to the ability to tune the porosity during the synthesis, and monoliths made from these carbon gels were successfully synthesized by the fiber templating method. The channel size and the wall thickness of the monoliths could be independently adjusted by changing the size and the amount of the template fibers, respectively (Fig. 3). The synthesized monoliths also had adequate mechanical strength to be activated, and samples with high BET surface area of over  $1600 \text{ m}^2 \text{ g}^{-1}$  could be obtained at a burn-off ratio (B.O.) of 47%, without altering the overall morphology. The synthesized monolith also showed high adsorption capacities of phenol, both in batch and continuous flow systems. It was found that the monoliths with channel sizes of up to  $100 \text{ }\mu\text{m}$  and wall thickness of up to  $70 \text{ }\mu\text{m}$  could effectively adsorb phenol in continuous flow systems at the superficial velocity of  $3 \text{ cm min}^{-1}$ . In these cases, the length of unused bed (LUB) for 20-mm samples were 5 mm or less. The results show the potential of the fiber templating method and the synthesized monoliths to be used in continuous adsorption.

**Fig. 3** Cross-sectional SEM images of FCGMs before activation, with channel sizes of 60–160  $\mu\text{m}$  and channel densities (in the form of void fraction  $\epsilon_v$ ) of 0.25–0.56

In Chapter 5, the optimal dimensions (channel size and wall thickness) of the monoliths were determined, and guidelines to determine the optimal dimensions of the monoliths were established. Finally, the simulated breakthrough curve of the monolith having optimal dimensions was compared to those of beds packed of spherical particles, and the monolith performed better than the packed beds, both in terms of mass transfer and hydraulic resistance. The results show the advantages of using the monolithic adsorbents with introduced straight microchannels, which the channel size and wall thickness could be tuned to optimize the performance in continuous adsorption.

Finally, Chapter 6 shows the general conclusions of this work. It is shown that monoliths with introduced straight microchannels have high potentials for the applications in continuous treatment of soluble aromatics in wastewater to improve the performance of conventional treatment systems.
