Abstract: We have carried out an experimental and theoretical study of CHA-zeolite supported indium (In)-oxo clusters that promote CH₄ activation at room temperature. X-ray absorption fine structure (XAFS) measurements indicate the formation of multinuclear In-oxo clusters by the O₂ activation of the In(I)-exchanged CHA zeolite prepared through reductive solid-state ion exchange (RSSIE). The structure of the In-oxo clusters and their locations were investigated in detail using *ab initio* thermodynamic analysis. The redox properties of the In species during RSSIE and the formation of the In-oxo clusters were also studied by temperature programmed reaction and *in situ* XAFS measurements. The reaction of CH₄ on the O₂-activated In-CHA zeolite was monitored using IR spectroscopy where adsorbed formic acid was generated at room temperature. The adsorption and C-H activation of CH₄ on our plausible model of the In-oxo clusters were theoretically investigated using density functional theory calculations. We found that CH₄ is likely to adsorb and react more easily on dinuclear In-oxo ions than on monomeric In-oxo ions and that the C-H bond cleavage reaction occurs via a heterolytic pathway rather than a homolytic pathway. This study reveals the potential of multinuclear In-oxo clusters as active sites for the transformation of CH₄ to oxygenates under mild reaction conditions.

1. Introduction

Multinuclear metal-oxo clusters, which are composed of a few metal and oxygen atoms, are expected to show unique catalytic differences from isolated metal ions and bulk metal oxides [1–24]. To date, there have been various studies on polyoxometalates stabilized by inorganic/organic ligands [2–8], metal-oxo clusters immobilized on solid supports (bulk metal oxides [9–12], zeolites [13–22], carbon nanotube [23], and metal-organic frameworks [24,25]), and gas-phase clusters vaporized by molecular beam and selected by mass spectroscopy [26,27]. Of these, aluminosilicate zeolite-supported metal-oxo clusters are promising from the viewpoint of precise synthesis, as well as catalytic application, because of their characteristics [28]; for example, the zeolite frameworks are well-defined and usually contain 6- to 12-membered rings consisting of tetrahedral SiO_4 and AlO_4 units linked through oxygen atoms. Paired Al sites are located on the ring, where multiply charged cations can be stabilized by two anionic sites (Si-O-Al). In addition, the high durability and easy handling of zeolites allow their applications in gas and liquid phase reactions. To date, several metal-oxo clusters in zeolites have been developed, making challenging transformations such as the C–H activation of CH_4 and light alkanes possible [13–20]. Cu-oxo clusters have been most extensively studied for CH_4 activation because they mimic the catalytic activity of copper-containing monooxygenase. For example, the oxidation of CH_4 to MeOH occurs on O_2 -activated Cu-exchanged ZSM-5, as reported by Groothaert *et al.* [14] and the dinuclear $[\text{Cu}(\text{O})\text{Cu}]^{2+}$ cluster was identified as the active site [15]. Cu-exchanged mordenite was also active for CH_4 conversion to MeOH, and a similar Cu dimer was proposed by Snyder *et al.* [16]. Subsequently, the groups of Lercher and Hensen identified the trinuclear $[\text{Cu}_3\text{O}_3]^{2+}$ cluster in mordenite by X-ray absorption fine structure (XAFS) analysis combined with density functional theory (DFT) calculations [17]. $[\text{Fe}_2(\mu_2\text{-OH})_2(\text{OH})_2(\text{H}_2\text{O})_2]^{2+}$ dimer [20] and $[\text{Ga}_2\text{O}_2]^{2+}$ dimer [18,19] in zeolites also have been found to be active for the oxidation [20] or dehydrogenation of light alkanes [18,19] based on a combination of experimental and theoretical studies. Other metal-oxo clusters of transition metal species, such as Ni, Co, Ag, and Au, have been studied experimentally and/or theoretically for CH_4 oxidation [21,22,29] while the study of typical metal-oxo clusters for CH_4 activation have been rarely reported.

Indium (In)-exchanged zeolites have the potential to activate the C–H bond of CH₄. It has been reported that reductive solid-state ion exchange (RSSIE) between In₂O₃ and H-form zeolites under a H₂ atmosphere around 700–800 K affords isolated In⁺ cations bound to the lattice oxygen anions [30,31]. Baba *et al.* reported the reaction of CH₄ with ethylene to propane at 673 K using In-exchanged ZSM-5 (In-ZSM-5), in which the isolated In⁺ cations with lattice oxygen anions were considered to cleave the C–H bond of CH₄ heterolytically to give methyl cation-like species [32]. In-exchanged zeolites have also been applied to the selective catalytic reduction (SCR) of NO with CH₄ and O₂ by Kikuchi *et al.* [33] and Szegedi *et al.* [34]. Both groups concluded that the CH₄ SCR reaction occurred on the InO⁺ sites in zeolites. Recently, Stepanov *et al.* revealed the activation of CH₄ on O₂-activated In-ZSM-5 at 453–573 K through the H/D exchange reaction [35] and transformation into surface species [36], where the isolated InO⁺ cation was proposed as an active site. These studies have demonstrated the activation of the C–H bond in CH₄ by In-exchanged zeolites and O₂-activated ones, while the formation of In-oxo clusters for CH₄ activation has not yet been reported.

Based on the above studies, we expect that multinuclear In-oxo clusters would be synthesized using the zeolites with well-defined paired Al sites and that these clusters would exhibit unique ability for CH₄ activation. In this work, the zeolite-supported In-oxo clusters for CH₄ activation under mild reaction conditions are described based on experimental and theoretical studies. To achieve this goal, a CHA zeolite was utilized as a support because its framework is more robust under thermal conditions than other zeolites [37,38]. This is advantageous to retain their paired Al sites without dealumination during RSSIE and O₂ activation. We found that multinuclear In-oxo clusters were formed by O₂ activation of In-exchanged CHA zeolites (InO_x-CHA) using X-ray absorption fine structure (XAFS) measurement. The formation of In-oxo clusters and their detailed structures are discussed on the basis of *ab initio* thermodynamics analysis. The redox properties of the In species during preparation of In-oxo clusters were also studied by temperature programmed reaction (TPR) and *in situ* XAFS measurement. Concerning CH₄ activation, the room temperature oxidation of CH₄ to formic acid on InO_x-CHA is demonstrated using *in situ* Fourier transform (FT)-IR measurements. The adsorption and activation energies for the cleavage of the C–H bond of CH₄ on plausible In-oxo dimers and monomer were theoretically evaluated by DFT calculations.

2. Experimental and theoretical methodology

2.1 Preparation of O₂-activated In-exchanged CHA zeolite (InO_x-CHA)

In-exchanged CHA (In(I)-CHA) was prepared through the impregnation and RSSIE as follows. First, 1.0 g of CHA zeolite (Tosoh, NH₄⁺-type, SiO₂/Al₂O₃ = 22.3, NH₄-CHA) was suspended in an aqueous solution containing 0.1 g of In(NO₃)₃•nH₂O (Kanto Chemical Co., Inc.). The water was evaporated from the mixture, and the mixture was dried in an oven and calcined at 773 K in air for 1 h, to afford In₂O₃ loaded on the CHA zeolite (denoted In₂O₃/CHA). Next, In₂O₃/CHA was treated with H₂ flow (20 mL min⁻¹) at 773 K for 30 min to promote RSSIE [30,31]. Hereinafter, the obtained In cation-exchanged CHA was denoted as In(I)-CHA. The O₂ activation of In(I)-CHA was conducted under O₂ flow (20 mL min⁻¹) at 773 K for 30 min. The O₂-activated In-exchanged CHA, InO_x-CHA, was obtained as a white powder.

2.2 Characterization

Powder X-ray diffraction (XRD) patterns were recorded on Rigaku Miniflex using Cu K α radiation. N₂ adsorption measurements were conducted by using an AUTOSOBB 6AG (Yuasa Ionics Co.). The loading amount of In was determined by energy dispersive X-ray fluorescence (EDX) spectrometry (Shimadzu EDX-700HS). H₂- and O₂-TPRs experiments were carried out using a BELCAT (MicrotracBEL). In₂O₃/CHA (approximately 50 mg) was pretreated at 773 K for 1 h under He. For H₂-TPR, In₂O₃/CHA was cooled to 373 K under He, and then the flow was changed to 5% H₂/Ar at a flow rate of 30 mL min⁻¹. For O₂-TPR, the above H₂-treated In₂O₃/CHA was cooled to 313 K under He, and then the flow was changed to 1% O₂/He at a flow rate of 30 mL min⁻¹. The temperature was increased to 773 K at 20 K min⁻¹, after which the temperature was maintained for 40 min. The H₂ consumption was monitored with a thermal conductivity detector. The O₂ consumption and the amount of gas consumed were investigated by a mass spectrometer (BEL Mass, (MicrotracBEL Inc.)). In K-edge XAFS data were collected in quick mode and recorded in transmission mode at the BL-01B1 and BL-14B2 stations attached to the Si(311) monochromator at SPring-8 (JASRI), Japan (Proposal Nos. 2018B1126 and 2018B1568). For *in situ* XAFS measurement, a flow-type cell connected to a flow reaction system was utilized. The X-ray absorption near-edge structure (XANES) and extended XAFS

(EXAFS) analyses were conducted using the REX ver. 2.5 program (Rigaku). The coordination numbers (CN) and interatomic distances (R) were estimated by curve-fitting analysis using In–O and In–In shell parameters obtained from reference samples of In_2O_3 . Scanning transmission electron microscopy (STEM) images were taken on a JEM-ARM200F microscope equipped with a JED-2300 EDX spectrometer (JEOL) at an acceleration voltage of 200 kV. The Cs-corrector CESCOR (CEOS) was used in STEM mode.

2.3 Reaction of CH_4 on $\text{InO}_x\text{-CHA}$

The IR spectroscopy study of the reaction of CH_4 was conducted with a JASCO FT/IR-4600 spectrometer equipped with a mercury cadmium telluride (MCT) detector using a flow-type IR cell connected to a flow reaction system. The IR disc of $\text{In}_2\text{O}_3/\text{CHA}$ (40 mg, 20 mm) was first dehydrated under N_2 flow at 773 K (90 mL min^{-1}) and then H_2 treatment (20 mL min^{-1}) followed by O_2 treatment (10% balanced with N_2 , 100 mL min^{-1}) was conducted at 773 K. After that a background spectrum was obtained under N_2 flow at 303 K (90 mL min^{-1}). Then, CH_4 (10%) was introduced to the sample, and the IR spectra were recorded. For control experiments, In_2O_3 (99.9%) was commercially purchased from Wako Pure Chemical Industries and then used.

2.4 DFT calculations

DFT calculations were carried out under the periodic boundary conditions using the Vienna *Ab initio* Simulation Package (VASP) [39,40]. The generalized gradient approximation by the Perdew–Burke–Ernzerhof (PBE) exchange-correlation functional was adopted [41], and the dispersion-corrected DFT-D3 method was employed to consider the van der Waals interactions. The Kohn–Sham equations were solved with the projector augmented wave (PAW) method. We checked the convergence of total energy of the models with respect to the number of k points where the consideration of the only Γ point was sufficient for Brillouin zone sampling (See Figure S1[†]). A modest Gaussian smearing of 0.05 eV was applied to the band occupations around the Fermi level, and the total energies were extrapolated to $\sigma \rightarrow 0$. The plane-wave cutoff energy was set to 500 eV, and spin–polarization was considered in all calculations. For geometry optimization, the lattice parameters were fixed ($a = b =$

13.675 Å, $c = 14.767$ Å, $\alpha = \beta = 90.0^\circ$, $\gamma = 120^\circ$ and $\text{Si/Al} = 17$),^[42] and the forces on atoms were minimized to be less than 0.03 eV/Å. The climbing image nudged elastic band (CI-NEB) method was used to locate the transition-state structures for the C–H bond cleavage of methane on the In-oxo species. The spring constant between adjacent images was set to 5.0 eV/Å², and the quasi-Newton algorithm was adopted for relaxing the geometry in the NEB approach while the cutoff was set to 400 eV due to the high computational cost.

XANES spectra were simulated for the DFT-optimized structures using the FDMNES software^[43,44]. For simulating the In foil, a unit cell consisting of two In atoms ($a = 3.309$ Å, $b = 3.309$ Å, $c = 5.016$ Å, and $\alpha = \beta = \gamma = 90.0^\circ$) was used, while the model of In₂O₃ consisting of 32 In atoms in the supercell ($a = b = c = 10.299$ Å and $\alpha = \beta = \gamma = 90.0^\circ$) was employed to simulate bulk In₂O₃. The simulated spectra were normalized based on the number of In atoms in each system.

Ab initio thermodynamic analysis was used to account for the presence of O₂ and H₂O as well as the effect of the temperature on the catalyst activation^[45]. We consider the following equilibrium reaction:

The corresponding reaction energy is represented as

$$\Delta E = E_{\text{In}_x\text{O}_m\text{H}_n/\text{CHA}} - xE_{\text{In(OH)/CHA}} - (1-x)E_{\text{CHA}_{2\text{H}}} - \frac{(2m-3x-n+2)}{4}E_{\text{O}_2} - \frac{(x+n-2)}{2}E_{\text{H}_2\text{O}} \quad (2)$$

where $E_{\text{In}_x\text{O}_m\text{H}_n/\text{CHA}}$ is the total energy of the CHA zeolite model containing In-oxo species. $E_{\text{In(OH)/CHA}}$ is the energy of the In-CHA model containing $[\text{In(OH)}]^{2+}$ ions to compensate for the negative charge of two Al atoms in the zeolite framework ($\text{In/Al} = 0.5$). $E_{\text{CHA}_{2\text{H}}}$, E_{O_2} , and $E_{\text{H}_2\text{O}}$ represent the computed energies of the CHA zeolite possessing two H atoms for charge compensation, gaseous water, and oxygen molecules, respectively. The accompanying change in the free energy, $\Delta\Gamma$, is defined as

$$\Delta\Gamma(T, p) = \frac{1}{A} \left[\Delta E - \frac{(2m-3x-n+2)}{2} \Delta\mu_{\text{O}} - \frac{(x+n-2)}{2} \Delta\mu_{\text{H}_2\text{O}} \right] \quad (3)$$

where A represents the area of the unit cell. The chemical potential, $\Delta\mu$, are described as

$$\Delta\mu_{\text{O}}(T, p) = \frac{1}{2} \left[\Delta\mu_{\text{O}_2}(T, p^0) + RT \ln \left(\frac{p_{\text{O}_2}}{p^0} \right) \right] \quad (4)$$

$$\Delta\mu_{\text{H}_2\text{O}}(T, p) = \Delta\mu_{\text{H}_2\text{O}}(T, p^0) + RT \ln \left(\frac{p_{\text{H}_2\text{O}}}{p^0} \right) \quad (5)$$

The temperature (T) and partial pressure (P_{O_2} or $P_{\text{H}_2\text{O}}$) dependencies of the chemical potentials of $\text{O}_2/\text{H}_2\text{O}$ were calculated from the differences in the enthalpy (H) and entropy (S) of each molecule with respect to the reference state at 0 K. The values of $H(T, p^0)$, $H(0 \text{ K}, p^0)$, $S(T, p^0)$, and $S(0 \text{ K}, p^0)$ in thermodynamic tables were used for standard pressure (1 atm) [46].

To discuss the molecular-orbital interactions, DFT calculations using a cluster model were carried out with the Gaussian 16 package [47]. The cluster model was constructed from the optimized structure mentioned above (a .mol file can be found in the ESI[†]). The hybrid B3LYP functional was used [48–50], and the SDD basis sets and D95** basis sets were applied for the In atoms and the Si, Al, O, and H atoms, respectively. In addition, the vdW-D2 correction was adopted. During geometry optimization, all atoms except for terminating H atoms were allowed to relax. The locations of the terminating H atoms were determined by prior geometry optimization where only the terminating H atoms were relaxed while all other atoms were fixed in the crystalline structure [51]. All optimized structure files are provided in the ESI[†].

3. Results and discussion

3.1 Morphologies and colors of the In-exchanged zeolites

To characterize the morphologies of the zeolites, we carried out XRD measurements and N₂ adsorption measurements of In₂O₃/CHA and InO_x-CHA. The XRD patterns of In₂O₃/CHA and InO_x-CHA were similar to that of H-CHA (prepared by calcination of NH₄-CHA at 773 K) (Figure 1(a)), which indicates that the crystal structure of CHA was maintained [52]. The specific surface areas (Table S1 in the ESI[†]), as determined by the Brunauer–Emmett–Teller (BET) method from N₂ adsorption isotherms (Figure 1(b)), of H-CHA, In₂O₃/CHA, and InO_x-CHA were 833, 785, and 710 m² g⁻¹, respectively. The pore volumes of H-CHA, In₂O₃/CHA, and InO_x-CHA were determined as 0.402, 0.378, and 0.344 mL g⁻¹, respectively. These results show that the pore structure of the CHA zeolites did not change during preparation. The smaller specific surface area and pore volume of InO_x-CHA than H-CHA and In₂O₃/CHA are ascribed to encapsulation of In species into zeolites. EDX analysis of In₂O₃/CHA revealed that the In loading amount was 3.2 wt%, which corresponds to In/Al ≈ 0.2. Figure 2 shows photographs of In₂O₃/CHA, In(I)-CHA, and InO_x-CHA. First, after impregnation followed by calcination, In₂O₃/CHA was a pale-yellow color (Figure 2(a)). During H₂ reduction of In₂O₃/CHA, the color changed from pale-yellow to white (Figure 2(b)), indicating the absence of aggregated In(0) metal species in In(I)-CHA. After the O₂ treatment of In(I)-CHA, the white color of the catalyst was maintained but differed from that of In₂O₃/CHA (Figure 2(c)), suggesting the formation of In-oxo species unlike In₂O₃.

Figure 2. Photographs of (a) $\text{In}_2\text{O}_3/\text{CHA}$, (b) $\text{In}(\text{I})\text{-CHA}$, and (c) $\text{InO}_x\text{-CHA}$.

3.2 STEM observation

The formation of highly dispersed In species was supported by STEM observation. The annular bright field and high-angle annular dark-field STEM (ABF- and HAADF-STEM, respectively) images of $\text{In}_2\text{O}_3/\text{CHA}$ show that many aggregated In_2O_3 species (about 10–30 nm) were present on the CHA zeolite (Figure 3). In contrast, the aggregated species was scarcely observed in the STEM images of $\text{InO}_x\text{-CHA}$ (Figures 4(a) and (b)). The distribution of In species was also determined by HAADF-STEM with EDX elemental mapping. The elemental mapping of $\text{InO}_x\text{-CHA}$ clearly shows the high dispersion of In species in the CHA zeolite (Figure 4). Note that aggregated In species formed during STEM observation (Figure 5). This result indicates that highly dispersed In species in the zeolite framework can easily be aggregated by the electron beam, making STEM observation difficult [53].

Figure 5. Aggregation of In species during STEM observation. (a) ABF- and (b) HAADF-STEM images of InO_x-CHA. The lower two images ((c) and (d)) were measured 12 min after collecting the upper two images.

3.3 H₂- and O₂-TPR measurements

The reduction profile of the In species in In₂O₃/CHA was investigated using H₂-TPR measurements. Figure 6(a) shows the H₂-TPR profiles. The reduction peak was observed around 573–773 K and the amount of H₂ consumed was determined to be 18 μ mol. This value is similar to the amount of In species in In₂O₃/CHA used for H₂-TPR (In: 15 μ mol). Lónyi *et al.* reported that the H₂-TPR profile during RSSIE between In₂O₃ and H-mordenite showed a reduction peak around 623–773 K. They also found that the molar ratio of the consumed H₂ and the In species are almost same [31]. Accordingly, the reduction peak observed after the H₂ treatment of In₂O₃/CHA corresponds to the occurrence of the RSSIE between In(III) ions and protons in CHA zeolite. The oxidation of In(I)-CHA was also carried out by O₂-TPR. The O₂-TPR profile (Figure 6(c)) showed a peak corresponding to the oxidation of reduced In species. Furthermore, H₂-TPR measurement was examined for InO_x-CHA where the position of reduction peak shifted toward lower temperature (473–723 K) from that in the case of In₂O₃/CHA (Figure 6(a) vs 6(b)). These observations suggest the formation of highly dispersed In-oxo species unlike In₂O₃, which is consistent with the results of the STEM observations.

Figure 6. H₂-TPR profiles of (a) In₂O₃/CHA and (b) InO_x-CHA. (c) O₂-TPR profile of In(I)-CHA.

3.4 XAFS measurements

To obtain insight into the In species in the In-exchanged CHA zeolites, *in situ* XAFS measurements were carried out. The normalized XANES spectra and Fourier transforms (FT) of the *k*³-weighted EXAFS spectra are summarized in Figures 7(a) and 7(c), respectively. First, the edge position of

In₂O₃/CHA ($E_0 = 27935.9$ eV) was almost the same as that of In₂O₃ powder ($E_0 = 27935.4$ eV) and different from that of In foil ($E_0 = 27932.6$ eV). The FT of EXAFS spectrum of In₂O₃/CHA showed three peaks, which were also observed in that of In₂O₃ powder (Figure 7(c)). The first peak can be attributed to the In–O shell, and the second and third peaks are assignable to two-types of In–In shells, respectively. These results are evidence for the existence of In₂O₃ species in In₂O₃/CHA.

After H₂ treatment (5% balance with He) of In₂O₃/CHA at 773 K, the absorption edge shifted to a lower energy ($E_0 = 27931.7$ eV). Figure 7(b) shows the XANES spectra during H₂ treatment in which three isobestic points were observed; these are marked with vertical dotted lines. These edge shift and isobestic points are similar to the observations made for the XANES spectra of Ga-exchanged zeolites during H₂ treatment in a previous paper [54], where the type of Ga species (isolated Ga⁺ cation or Ga-hydride species) is controversial. Hock *et al.* claimed that the edge shift can be interpreted as evidence of Ga-hydride species on the basis of a comparison of XANES spectra with organometallic model compounds [55]. In contrast, Lercher *et al.* concluded that Ga⁺ cation was selectively formed based on the H₂-TPR measurement [56]. Considering the RSSIE between In₂O₃ and H-zeolites reported in previous papers [30,31], the energy shift in In K-edge XANES spectra can be ascribed to the reduction of In³⁺ species (In₂O₃) to In⁺ cations. However, the simulated XANES spectra suggested the formation of In-hydride (In⁺-H⁻) species [57–59] rather than In⁺ cations (Figure S2[†]). The speciation of In after RSSIE is currently under study using other spectroscopic and theoretical methods.

After an He purge followed by O₂ treatment (5% balance with He) of In(I)-CHA at 773 K, the absorption edge returned to a similar value to that of In₂O₃ ($E_0 = 27934.7$ eV), indicating that In⁺ ions were oxidized to In³⁺ species (Figure 7(a)). In the FT of the EXAFS spectrum of InO_x-CHA (Figure 7(c)), the two peaks assignable to In–O and In–In shells were observed, which is different from the cases of In₂O₃ and In₂O₃/CHA. The curve fitting analysis indicated that the CNs are 4.9 and 2.3, respectively (Table 1). From the results obtained from XAFS measurements, multinuclear In-oxo clusters were generated in the CHA zeolites. Thus, in conclusion, the In₂O₃ loaded on H-CHA was reduced by H₂ treatment to afford isolated In⁺ ions in the CHA zeolite through RSSIE and, then, the dispersed In⁺ ions reacted with O₂, resulting in the formation of In-oxo clusters.

3.5 *Ab initio* thermodynamic analysis

We employed an *ab initio* thermodynamic approach [60] to predict the structures of the In-oxo clusters in InO_x-CHA. This approach has been utilized for predicting the structures of the key multinuclear metal-oxo clusters of Cu, Fe, and Al cations in zeolites [17,45,61–64]. Three types of paired Al sites were examined as coordination sites of the In-oxo clusters. The first type possesses two Al sites that are separated by three Si centers in an eight-membered ring (8MR) and has a connectivity distance of three, denoted as the forth-nearest-neighbor site, 8MR(4NN). The other two are represented as 8MR(3NN) and 6MR(3NN) (Figure 8). Our computational data set includes one monomer, two dimers, one trimer and three tetramers. Details of models are provided in the ESI[†]. To reflect the reaction conditions of the O₂ treatment of In(I)-CHA, we have shown the computational free energies for the formation of In-oxo ions (Figures 9(a)–(c)) and the phase diagram representing the lowest-energy species (Figures 9(d)–(f)) at 800 K as a function of O₂ and H₂O chemical potentials ($\Delta\mu_{\text{O}_2}$ and $\Delta\mu_{\text{H}_2\text{O}}$, respectively). $\Delta\mu_{\text{O}_2}$ and $\Delta\mu_{\text{H}_2\text{O}}$ are translated into partial pressure scales (P_{O_2} and $P_{\text{H}_2\text{O}}$, respectively) at 800 K in the phase diagram.

In the phase diagram for the 8MR(4NN) site (Figure 9(d)), the equilibrium In-oxo structure is sensitive to the value of $\log(P_{\text{H}_2\text{O}})$, and the [In₂O₂]²⁺ ion (yellow) is the lowest-energy In-oxo ion at the lowest H₂O partial pressure. As $\log(P_{\text{H}_2\text{O}})$ increases, the [In₂O₂]²⁺ ion changes to a tetrameric structures, such as [In₄O₄]²⁺ (gray) and [In₄O₄(OH)₂]²⁺ ions (green), and [In₂(OH)₄]²⁺ ion (blue) is the lowest-energy In-oxo ion at high H₂O partial pressures. At a $\log(P_{\text{O}_2})$ of around -1 or 0 and a low H₂O partial pressure, corresponding to 10% or 100% O₂ flow in dry conditions, the free energy for the formation of the [In(OH)]²⁺ ion is only slightly higher than that of [In₂O₂]²⁺ ion, whereas those of other In-oxo ions are much higher, as shown in Figure 9(a). These results indicate that the [In₂O₂]²⁺ ion is a candidate In-oxo cluster on 8MR(4NN) sites under O₂ condition. Concerning the 8MR(3NN) site, although [In(OH)]²⁺ ion (red) is the lowest-energy In-oxo ion at low H₂O pressures (Figure 9(e)), the free energy for the formation of the [In₂O₂]²⁺ ion is close to that of the [In(OH)]²⁺ ion and much lower than those of the other In-oxo ions (Figure 9(b)), indicating that the [In₂O₂]²⁺ ion is a plausible In-oxo structure for the 8MR(3NN) site. In contrast, for the 6MR(3NN) site, the [In(OH)]²⁺ ion is the most stable structure under all O₂ and H₂O partial pressures (Figures 9(c) and 9(f)). From the phase diagrams, we suggest

that multinuclear In-oxo clusters are formed at paired Al sites on 8MR, and the $[\text{In}_2\text{O}_2]^{2+}$ ion is the most plausible structure among the considered multinuclear clusters. Hereinafter, we consider $[\text{In}_2\text{O}_2]^{2+}$ on 8MR(4NN) and 8MR(3NN) and $[\text{In}(\text{OH})]^{2+}$ on 6MR(3NN) as model dimeric and monomeric In-oxo ions for further discussion.

Figure 8. CHA unit cell and Al configurations investigated in periodic DFT calculations. Ovals highlight the locations of 8MR and 6MR.

Figure 9. Free energy ($\Delta\Gamma$) for the formation of the In-oxo ions in CHA (top) and phase diagram showing the lowest-energy In-oxo ions (bottom) as a function of O_2 and H_2O chemical potentials ($\Delta\mu_{\text{O}_2}$ and $\Delta\mu_{\text{H}_2\text{O}}$, respectively) on (a,d) 8MR(4NN), (b,e) 8MR(3NN), and (c,f) 6MR(3NN).

The optimized structures for $[\text{In}_2\text{O}_2]^{2+}$ at 8MR(4NN) and 8MR(3NN) sites (denoted as $[\text{In}_2\text{O}_2]^{2+}$ -8MR(4NN) and $[\text{In}_2\text{O}_2]^{2+}$ -8MR(3NN)) and for $[\text{In}(\text{OH})]^{2+}$ at 6MR(3NN) ($[\text{In}(\text{OH})]^{2+}$ -6MR(3NN)) are

shown in Figure 10. The In–In distances for $[\text{In}_2\text{O}_2]^{2+}$ -8MR(4NN) is 2.92 Å, which is very similar to that in $[\text{In}_2\text{O}_2]^{2+}$ -8MR(3NN) (2.91 Å), despite the obvious difference in the Al–Al distances (7.88 and 7.23 Å for $[\text{In}_2\text{O}_2]^{2+}$ -8MR(4NN) and $[\text{In}_2\text{O}_2]^{2+}$ -8MR(3NN), respectively). The In–O distances range from 2.07 to 2.10 Å for both $[\text{In}_2\text{O}_2]^{2+}$ ions. These In–In and In–O distances are different from the case of $[\text{Ga}_2\text{O}_2]^{2+}$ ions in zeolites reported by Hensen *et al.* [19] where the Ga–Ga and Ga–O distances were calculated to be about 2.49–2.59 and 1.84–1.89 Å, respectively. The In–O–In angles for $[\text{In}_2\text{O}_2]^{2+}$ -8MR(4NN) and $[\text{In}_2\text{O}_2]^{2+}$ -8MR(3NN) are about 88–89°. This value is slightly larger than the Ga–O–Ga angle in $[\text{Ga}_2\text{O}_2]^{2+}$ ions (about 84–88°). For $[\text{In}(\text{OH})]^{2+}$ -6MR(3NN), the In–O distance of $[\text{In}(\text{OH})]^{2+}$ is 2.02 Å and the Al–Al distance is 5.88 Å. The shorter Al–Al distance in 6MR(3NN) compared to those in 8MR(4NN) and 8MR(4NN) might be one of the reasons why monomeric $[\text{In}(\text{OH})]^{2+}$ ions are more stable among the other In-oxo ions. As demonstrated above, $[\text{In}_2\text{O}_2]^{2+}$ ions are expected to be the most stable In-oxo ions on paired Al sites in 8MR.

Figure 10. Optimized structures of (a) $[\text{In}_2\text{O}_2]^{2+}$ -8MR(4NN), (b) $[\text{In}_2\text{O}_2]^{2+}$ -8MR(3NN), and (c) $[\text{In}(\text{OH})_2]^{2+}$ -6MR(3NN).

3.6 Experimental and theoretical investigation for activation of CH_4 on In-oxo clusters

The development of effective catalysts for CH_4 activation under mild conditions is challenging because of the high stability of C–H bonds in CH_4 , and various experimental and theoretical studies in this research area have been carried out [29,65–83]. To explore the ability to activate CH_4 of In-oxo clusters supported in CHA, the adsorbed species generated during the reaction of CH_4 on InO_x -CHA at room temperature were studied by *in situ* IR measurements (Figure 11). The FT-IR spectrum contains a

peak at 1379 cm^{-1} and a band around 1700 cm^{-1} after 10% CH_4 purge for 100 min followed by an N_2 purge. The first peak can be assigned to C–H bending of adsorbed formic acid [84], and the latter peak was deconvoluted into two peaks at 1710 and 1630 cm^{-1} , which can be attributed to the C=O stretching of adsorbed formic acid and water [84], respectively. The formation of formic acid was supported by the FT-IR measurement after adsorption of formic acid on H-CHA where similar two peaks were observed (Figure S3 in the ESI[†]). The CH_4 -TPR of $\text{InO}_x\text{-CHA}$ revealed that neither CO_2 nor CO was detected at room temperature, indicating the occurrence of selective oxidation of CH_4 to formic acid. We tried to extract the adsorbed formic acid using D_2O for determination by ^1H NMR measurement according to the previous paper [85], but any peak was not observed in the NMR spectrum, which might be due to difficulty in extraction from the small pore of CHA zeolites. In the control experiments using $\text{In}_2\text{O}_3/\text{CHA}$ and In_2O_3 instead of $\text{InO}_x\text{-CHA}$, the spectra did not contain these peaks. The above results show that CH_4 was oxidized to formic acid at room temperature over the In-oxo clusters.

Figure 11. (a) FT-IR spectra during the reaction of CH_4 on $\text{InO}_x\text{-CHA}$ at room temperature. (b) Curve-fitting of the band around $1800\text{--}1600\text{ cm}^{-1}$ in the IR spectrum after N_2 purge.

The C–H bond cleavage is generally regarded as the rate-determining step in the reactions of CH_4

on most heterogeneous catalysts [74], and much effort has been devoted to the study of activation of C–H bond of CH₄ through experimental and theoretical approaches [76,79,80,82,86]. We also investigated the reactivities of the possible In-oxo ions, [In₂O₂]²⁺-8MR(4NN), [In₂O₂]²⁺-8MR(3NN), and [In(OH)]²⁺-6MR(3NN), for the C–H bond cleavage of CH₄ using DFT calculations, and the reaction energy diagrams and geometrical parameters are shown in Figure 12 and Table 2, respectively. The adsorption energies of CH₄ on [In₂O₂]²⁺-8MR(4NN) and [In₂O₂]²⁺-8MR(3NN) are similar ($E_{\text{ads}} = -43.7$ and -41.8 kJ/mol, respectively) and larger than that on [In(OH)]²⁺-6MR(3NN) ($E_{\text{ads}} = -18.9$ kJ/mol). As shown in Figure 12 and Table 2, the shortest In–C distances for [In₂O₂]²⁺-8MR(4NN), [In₂O₂]²⁺-8MR(3NN), and [In(OH)]²⁺-6MR(3NN) are 2.91, 2.87, and 5.36 Å, respectively. In contrast, the four C–H bond distances of the CH₄ molecules adsorbed on each In-oxo ions are almost the same, and the average distance is about 1.10 Å. The H–C–H angles directed toward the In cation of [In₂O₂]²⁺-8MR(4NN) and [In₂O₂]²⁺-8MR(3NN) are 114.3° and 112.4°, respectively. These values are larger than the H–C–H angle of isolated CH₄ (109.7°). These results suggest that CH₄ adsorbs on [In₂O₂]²⁺ ions in an η^2 -like fashion, which results in a distorted CH₄ structure. Similar M–H and C–H bond distances and H–C–H angles were reported by Kuroda *et al.* in their theoretical studies of CH₄ activation by Zn and Mg cations in zeolites [87]. In contrast, the H–C–H angle for [In(OH)]²⁺-6MR(3NN) (109.0°) is very close to that in isolated CH₄.

Figure 12. Reaction energy diagrams of the intermediates and transition states for the activation of CH₄ by [In₂O₂]²⁺-8MR(4NN) (green), [In₂O₂]²⁺-8MR(3NN) (blue), [In(OH)₂]²⁺-6MR(3NN) (red), and [In₄O₄]²⁺-8MR(4NN) (orange). Optimized structures of the intermediates and transition states for [In₂O₂]²⁺-8MR(4NN) (bottom) and [In(OH)]²⁺-6MR(3NN) (top) are included in the figure.

Table 2. Geometrical parameters (distances in Å and bond angles in degrees) for adsorption (Ads), transition-state (TS), dissociation (Dis) structures of [In₂O₂]²⁺-8MR(4NN), [In₂O₂]²⁺-8MR(3NN), [In(OH)]²⁺-6MR(3NN), and [In₄O₄]²⁺-8MR(4NN).

Following adsorption, CH₄ is activated by the weakening of the C–H bond via a transition state (TS). The C–H bond distances in the TS for [In₂O₂]²⁺-8MR(4NN), [In₂O₂]²⁺-8MR(3NN), and [In(OH)]²⁺-6MR(3NN) are almost the same (1.38, 1.37, and 1.35 Å, respectively), whereas the activation energies for [In₂O₂]²⁺-8MR(4NN) and [In₂O₂]²⁺-8MR(3NN) are much lower than that for [In(OH)]²⁺-6MR(3NN) (E_a = 85.9 and 85.9 vs 117.5 kJ/mol, respectively). After the dissociation of the C–H bond, an O–H bond is formed at the bridging O atom, and the resulting CH₃ group forms an In–CH₃ fragment for [In₂O₂]²⁺-8MR(4NN) and [In₂O₂]²⁺-8MR(3NN). In the case of [In(OH)]²⁺-6MR(3NN), water is formed from the OH group, accompanied by the formation of an In–CH₃ bond [88]. All the In–C distances are 2.17 Å, which is very similar to that in the In(CH₃)₃ model calculated by Gueorguiev *et al.* [89]. The reactions of the C–H bond cleavage for [In₂O₂]²⁺-8MR(4NN) and [In₂O₂]²⁺-8MR(3NN) are more exothermic (ΔE = 123.4 and 148.6 kJ/mol) than that of [In(OH)]²⁺-6MR(3NN) (28.0 kJ/mol). These results suggest that CH₄ is likely to adsorb and react more easily on the [In₂O₂]²⁺ ions rather than [In(OH)]²⁺ ions.

Furthermore, the reactivity of a possible higher oligomer, [In₄O₄]²⁺-8MR(4NN) (the optimized structure is shown in Figure S4[†]), was investigated by DFT calculation and compared with [In₂O₂]²⁺-8MR(4NN) and [In(OH)]²⁺-6MR(3NN) as dimeric and monomeric In-oxo ions, respectively. The C–H bond cleavage over [In₄O₄]²⁺-8MR(4NN) is exothermic (ΔE = 98.6 kJ/mol) and affords an O–H bond and an In–CH₃ fragment as is the case for [In₂O₂]²⁺-8MR(4NN) (Figure 12). The adsorption energy of CH₄ on [In₄O₄]²⁺-8MR(4NN) is -29.3 kJ/mol, which is moderate among the monomeric, dimeric and tetrameric In-oxo ions explored in this study. The calculated activation energy for [In₄O₄]²⁺-8MR(4NN) is much higher than that for [In₂O₂]²⁺-8MR(4NN) (E_a = 111.4 vs 85.9 kJ/mol, respectively) and lower than that for [In(OH)]²⁺-6MR(3NN) (117.5 kJ/mol). This comparison based on DFT calculation showed that dimeric In-oxo clusters are more reactive than tetrameric ones. We also calculated the partial charge (q) of O and In atoms ($q(O)$ and $q(In)$, respectively) to investigate the correlation between of E_a and

$q(O)/q(In)$ for four In-oxo ions. The plots in Figure 13 show that E_a decreases linearly with a decrease of $q(O)$ (Figure 13(a)) while no obvious correlation is found between E_a and $q(In)$ (Figure 13(b)). The similar $q(O)$ dependency of the activation energy was observed in DFT calculation for C–H activation on bimetallic Co–M oxide clusters reported by Gagliardi et al. [90]. These results showed that the difference of reactivity among monomeric, dimeric, and tetrameric In-oxo ions is ascribed to the difference of nature of bridging O atom, demonstrating the potential of partial charge of bridging O atom as a useful descriptor to rationalize and predict the reactivity of metal-oxo clusters.

Figure 13. Plots of the C–H activation energy (E_a) against partial charge of (a) bridging O atom and (b) In. For (a), linear regression line $y = -304.06x - 191.45$, $R^2 = 0.9246$.

To gain some insight into the adsorption and activation mechanisms of CH₄ on [In₂O₂]²⁺-8MR(4NN), we analyzed the molecular orbitals. It is considered that there are two main interactions between the adsorbates and active metal centers: A) charge transfer interactions from the occupied orbital of the adsorbate to an empty orbital of the metal center and B) charge transfer interactions from the occupied orbital of the metal center to the empty orbital of the adsorbate [86,91]. The energy gap between the lowest occupied molecular orbital (LUMO) of [In₂O₂]²⁺-8MR(4NN) and the highest occupied molecular orbital (HOMO) of CH₄ is 8.36 eV, which is smaller than that between the HOMO of [In₂O₂]²⁺-

8MR(4NN) and the LUMO of CH₄ (10.26 eV) (Figure 14(a)), indicating that the charge transfer from the HOMO of CH₄ to the LUMO of [In₂O₂]²⁺-8MR(4NN) is more likely to occur. As shown in Figure 14(a), the LUMO of [In₂O₂]²⁺-8MR(3NN) is localized at the In1 cation where CH₄ interacts as indicated in the optimized structures (Figure 12). The charge density difference for CH₄ adsorption on [In₂O₂]²⁺-8MR(4NN) (Figure 14(b)) shows the main transfer of electron density from the C–H bonds to the region between the C–H bond and the In1 cation, indicating the heterolytic cleavage of the C–H bond [87,92,93]. Heterolytic cleavage is supported by a comparison of the energy diagrams (Figure S5[†]), which show that the activation energy for the radical intermediate is significantly larger (298.3 kJ/mol) than that for heterolytic cleavage (85.9 kJ/mol, Figure 12) [92]. It is well-known that the activation of CH₄ and other light alkanes over transition metal surfaces and multinuclear Cu-oxo and Fe-oxo clusters is initiated by the homolytic cleavage of C–H bonds to give radical intermediates [15,17,20,51,77,82,83]. Although there are some reports suggesting the heterolytic cleavage of C–H bonds of those substrates by using Zn or Ga ion-exchanged zeolite materials [87,92,93], the present In-CHA system still serves as a rare example that can activate CH₄ through the heterolytic cleavage of the C–H bond.

Figure 14. (a) Molecular orbitals of [In₂O₂]²⁺-8MR(4NN) and CH₄. Only selected orbitals are depicted for clarity. (b) Isosurface plot of the charge density difference from isolated CH₄ and [In₂O₂]²⁺-8MR(4NN): yellow, negative charge accumulation; cyan, negative charge depletion.

4. Conclusion

The present study shows that O₂ treatment of In-exchanged CHA zeolites at 773 K affords multinuclear In-oxo clusters that can cleave the C–H bond of CH₄ at mild temperatures. TPR and *in situ* XAFS measurements reveal that the reduced In species are immobilized on CHA through RSSIE and then react with O₂ to form In-oxo clusters. The detailed structure of the In-oxo clusters was predicted by *ab initio* thermodynamics analysis. The obtained phase diagrams indicate that [In₂O₂]²⁺ is the most probable cluster under atmospheric O₂ pressure and dry conditions at the paired Al sites on 8MR. Concerning CH₄ activation, InO_x-CHA activated and oxidized CH₄ at room temperature to afford the adsorbed formic acid, as revealed by *in situ* FT-IR measurements. We also compared the adsorption and activation energies for the C–H bond cleavage of CH₄ over [In₂O₂]²⁺, [In₄O₄]²⁺, and [In(OH)]²⁺ ions formed in the zeolite using DFT calculations, and [In₂O₂]²⁺ was found to be the most active. The molecular orbital analysis revealed that the adsorption of CH₄ is derived from the charge transfer from the HOMO of CH₄ to the LUMO of [In₂O₂]²⁺-8MR(4NN), and the C–H bond cleavage reaction occurs via a heterolytic pathway rather than a homolytic pathway. The creation of multinuclear In-oxo clusters in various zeolites and their application to transformation of CH₄ to higher-value compounds are under investigation.
