Cover title: Cost effectiveness of Drive and Retrieve System

Key words: Cost-Effectiveness, Geographic Information System, Ischemic Stroke, Endovascular

Thrombectomy, Drive and Retrieve System

Abstract

Background and Purpose: Although endovascular thrombectomy combined with recombinant tissue-type plasminogen activator is effective for treatment of acute ischemic stroke, regional disparities in implementation rates of those treatments have been reported. Drive and retrieve system, where a qualified neurointerventionist travels to another primary stroke center for endovascular thrombectomy, has been practiced in parts of Hokkaido, Japan. This study aims to simulate the cost-effectiveness of the drive and retrieve system, which can be a method to enhance equality and cost-effectiveness of treatments for acute ischemic stroke.

Materials and methods: The number of patients who had acute ischemic stroke in 2015 is estimated. Those patients are generated according to the population distribution, and thereafter patient transport time is analyzed in the three scenarios (1) 60-minute drive scenario, (2) 90-minute drive scenario, in which the drive and retrieve system operates within 60-minute or 90-minute driving distance (3) without the system, using geographic information system. Incremental cost-effectiveness rate, quality adjusted life years, and medical and nursing care costs are estimated from the analyzed transport time.

Findings: The incremental cost-effectiveness rate by implementing the system was dominant. Cost reduction of \$213,190 and \$247,274 was expected in 60-minute and 90-minute drive scenario, respectively. Such benefits are the most significant in Soya, Emmon, Rumoi, and Kamikawahokubu medical areas.

Conclusion: The drive and retrieve system could enhance regional equality and cost effectiveness of ischemic stroke treatments in Hokkaido, which can be achieved using existing resources. Further studies are

A Cost-effectiveness Simulation of Drive and Retrieve System in Hokkaido

required to clarify its cost-effectiveness from hospital perspective.

Introduction

Stroke is the fourth largest cause of death in Japan, and accounts for the largest proportion of patients with nursing care needs [1]. Approximately 26.9% of patients with nursing care needs in Japan have had stroke [2]. In the aging society of Japan, where medical and nursing care costs have been increasing, the viewpoint of cost-effectiveness of stroke treatments needs to be considered. The stroke databank (2016) reported that ischemic stroke accounted for 68.7% of all types of strokes [3]. Therefore, it is necessary to consider cost-effective management of ischemic stroke treatments.

Recombinant tissue-type plasminogen activator (rt-PA) and endovascular thrombectomy have been known as effective treatments of acute ischemic stroke (AIS) [4,5]. Several randomized controlled trials (RCTs) and meta-analysis have reported the effectiveness of these treatments [6-8]. Despite the efficacy, disparity in implementation rates of the treatments between rural areas and urban areas have been reported due to their time limits [9, 10]. Furthermore, the later the reperfusion is performed, the worse the outcome will be [11]. Therefore, efforts should be made to shorten the processing time between symptom onset and treatment. Hokkaido, a prefecture in Japan, has the largest land area with lowest population density. Moreover, Hokkaido has the highest number of secondary medical areas among all the prefectures in Japan [12], which are regional units that provide in-hospital medical services, including stroke care. Disparities in medical services [13] and stroke treatments [14, 15] have been reported in Hokkaido. Although it is desirable that stroke care is provided equally in all medical areas, it is not always possible due to lacking medical resources such as Computed Tomography, Magnetic Resonance Imaging, electrocardiogram, and qualified

neurointerventionists for endovascular thrombectomy. Therefore, a system for medical cooperation that specializes in endovascular treatment for AIS is needed to ensure prompt initiation of treatment and to reduce the time from onset to reperfusion. Many such systems have been proposed till date. For example, some studies have evaluated the "drip and ship method" [16], whereas others have reported better results with centralized direct transport, or the "mothership" method, because of its reduced transportation time and potential reduction in mortality rate [17]. Several studies have proposed the "drive and retrieve system," where neurointerventionists, who work at comprehensive stroke centers, travel to primary stroke centers to provide endovascular thrombectomy. By implementing the drive and retrieve system, more patients will be eligible for these treatments, and better outcomes can be expected due to earlier treatment initiation [18]. To provide data to achieve equal and efficient treatments of patients with AIS, this study simulates the effect of the drive and retrieve system on accessibility to rt-PA and endovascular thrombectomy, and assesses the cost effectiveness of drive and retrieve system from the perspective of medical and nursing care expenditures.

Materials and Methods

Subjects and outcomes

The subjects in this study are a virtual cohort of patients with AIS in Hokkaido in 2015 (for population distribution and secondary medical areas in Hokkaido, refer to Fujiwara et al. (2017) [15]). The analysis period is 3 years from the patients' onsets. Solitary island areas are excluded in the analysis. Three scenarios, with (1) 60-minute and (2) 90-minute drive and retrieve systems (60-minute scenario and 90-minute scenario) where qualified neurointerventionists travel to primary stroke centers for endovascular

thrombectomy within 60 minute or 90 minute drive distance (Spoke hospitals) after patients' onsets, and (3) without the system (the current scenario) are compared and cost effectiveness achieved by implementing the drive and retrieve system is assessed. The primary outcome is incremental cost-effectiveness rate (ICER), which is calculated by dividing incremental costs with incremental Quality-adjusted life years (QALY). ICER is the standard measurement for cost effectiveness at the National Institute of Health and Care Excellence in Britain [19], Japan [20], and elsewhere. In this study, ICER is evaluated by the 5,000,000 JPY-per-QALY threshold (approximately 44, 228\$), which is suggested by Ministry of Health, Labour, and Wealth for evaluating cost effectiveness in Japan [21]. Cost gain (reduction) by the system is also analyzed. The costs include medical costs and nursing costs up to 3 years after symptom onset, and the gained QALYs are estimated for the same period. Per-time costs of the Drive and retrieve system are also calculated for each secondary medical area by dividing the incremental cost by the number of patients whose transport time is shorten. Data on the 29 hospital where neurointerventionists are present (Hub hospitals) and on 108 spoke hospitals (without neurointerventionists but equipped for the treatment) is obtained from the websites of The Japanese Society for Neuroendovascular Therapy [22] and Hokkaido Medical Plan [13], respectively.

Patient generation

First, we estimate the number of stroke patients from the incidence data of Patient Survey from the Ministry of Health, Labor and Welfare, and the population (2014) [22]. Then the number of ischemic stroke patients is estimated using data from the Stroke databank, a Japanese nationwide database of stroke patients in Japan [3]. Thereafter, the number of patients is randomly allocated to each 1km² mesh of the geographic

information system (GIS), in accordance with its population. This allocation is repeated 10,000 times, and the average number for each mesh is used as the number of patients who are generated on ArcGIS Desktop10 (ESRI Inc.) using random point generation.

Transport time analysis

Transport time is analyzed using closest facility analysis of GIS. The sum of the time when an ambulance arrives at a patient location and the time of arrival from the patient location to a hospital is defined as transport time. Ambulance locations are obtained from National Land Numerical Information (2015) [23].

To assess the transport time in 60-minute and 90-minute scenarios, the 76 spoke hospitals which are within 60-minute driving distance from the 29 hospitals where neurointerventionists work (Hub hospitals) are identified using “object identifier matrix” function of GIS. Likewise, the 84 spoke hospitals within 90-minute driving distance from the hub hospitals are identified. The transport time in each of the 3 scenarios is then analyzed. Patients are divided into 4 groups depending on the following time windows: (1) those transported within 1 hour (2) those transported between 1–2 hours (3) those transported between 2–3 hours, and (4) those transported more than 3 hours after symptom onset.

Patient outcome estimation

The drive and retrieve system aims to provide early rt-PA and endovascular thrombectomy for as many patients as possible. Our analysis attempts to study the outcomes that patients gain through earlier reperfusion, by using data from the Highly Effective Reperfusion evaluated in Multiple Endovascular Stroke Trials (HERMES) collaboraten study [24], a meta-analysis of 5 RCTs [25-29]. In the HERMES study, rt-

A Cost-effectiveness Simulation of Drive and Retrieve System in Hokkaido

PA was used for more than 83% of the patients treated with endovascular thrombectomy [24]. Furthermore, the guideline for using mechanical thrombectomy device in Japan (2015) stated that rt-PA should be given the first priority [5]. These 2 treatments should be comprehensively considered. Therefore, it is assumed that endovascular thrombectomy is implemented after rt-PA treatment. In this study, rt-PA time window (4.5 hours) is used for patient severity estimate [30]. Although the time limit is 4.5 hours after symptom onset, Spokorny et al. (2015) reported that onset time tended to be estimated around 30 minutes earlier than the actual onset time [31]. In addition, the Japan Stroke Society (2015) recommends that rt-PA be administered within 1 hour after door time [4]. Considering the uncertainty in onset time [31] and the time until rt-PA administration [4], it is assumed that patients whose transport time is within 3 hours after symptom onset are eligible for rt-PA, and subsequently endovascular thrombectomy. According to a report from Japan Stroke Association, it is assumed that rt-PA and endovascular thrombectomy implementation rates are 16.9% for those transported within three hours [32].

For severity estimation, modified Rankin Scale (mRS) at 90 days after symptom onset is used. The data on reperfusion time and mRS at 90 days are obtained from the HERMES study (Table1) [11]. According to the transport time groups, the patients are given the expected mRS stage distributions (Table 1). It is assumed that the patient severity distributions will not change during the study period.

Table1. Expected mRS distribution at 3 months after onset [11]

eligibility for rt-PA and endovascular thrombectomy	time window	Rates of patients at each mRS stage (%)						
		0	1	2	3	4	5	6

eligible	transported between 0-1 hour after onset	11.0	21.6	24.5	19.4	11.6	5.0	7.0
eligible	transported between 1-2 hour after onset	9.6	19.8	24.0	20.2	12.7	5.7	8.0
eligible	transported between 2-3 hour after onset	8.4	18.1	21.3	20.9	13.8	6.3	9.2
not eligible		3.6	6.2	12.5	8.7	31.2	15.0	22.5

rt-PA: Recombinant tissue-type plasminogen activator, mRS: modified Rankin Scale

Table 1 footnotes

Table1 shows the expected mRS distributions used in the simulation, which is quote from [11].

It is assumed that patient severity varies with patient transport time and eligibility for rt-PA and subsequent endovascular thrombectomy.

Medical and nursing care costs

Medical costs as well as nursing care costs are included in the cost analysis, since stroke patients are likely to suffer from post-stroke disability [33]. In Japan, official rates for medical costs and nursing care costs are applied throughout the country. In this study, these costs are estimated based on the expected mRS distribution. First, data for per-patient medical cost is obtained from Japan Stroke Databank (Table 2) [3].

Nursing care services are insured based on patient care needs, which are assigned based on patients' severity.

The care needs are divided into 7 categories (support levels 1 and 2, and care levels 1–5), with care level patients severer than support level patients. Higher levels mean that patients tend to have severer disability

[34]. In this study, the care needs of the patients (Table 2) and nursing care costs are estimated from Statistics of Medical Care Activities in Public Health Insurance by the Ministry of Labour, Health, and Welfare [35], in accordance with a previous research [33]. The estimated per-year nursing care costs were \$3,092 for Support Level 1, \$5,285 for Support Level 2, \$11,311 for Care Level 1, \$15,288 for Care Level 2, \$22,389 for Care Level 3, \$26,689 for Care Level 4, and \$30,939 for Care Level 5. Hattori et al. (2012) reported that patients at different mRS stages have different utilization rates of nursing care services [36], that is, severe patients are likely to utilize nursing care services. It is assumed that patients utilize nursing care services at the rates shown in Table 2. This process of estimating medical costs and nursing care costs is applied to patients for each transport time window, and per-patient cost expectations are calculated for each of the transport time windows in each scenario. The expected medical costs and nursing care costs are converted to US dollars at the currency exchange rate as of November 21, 2018 and are discounted at 2% per year [20].

Table 2. Data on costs, care need level, and nursing care utilization rate, and QALY for each mRS stage used in the simulation

	mRS stage						
	0	1	2	3	4	5	6
Total medical costs (\$US) [3]	7,626	10,286	14,632	16,848	20,218	28,642	24,031
Care need level [32]	No care	Support Level1	Support Level 2	Care Level 1	Care Level 2 or 3 *	Care Level 4 or 5 *	No care
The rate at which nursing care sevicees are utilized (%) [35]	0	26.1	91.8	98.5	100	100	0
QALYs [35]	0.89	0.797	0.65	0.588	0.363	0.092	0

Table2 footnotes

Table 2 shows the data on total medical costs [3], care need levels [32], the rates at which nursing care services [35], and Quality Adjusted Life Years (QALYs) for patients at each mRS stage [35] used in the simulation.

It is assumed that those parameters vary with patient mRS stages.

QALY

As mentioned above, QALY is used as a measurement of patient outcome. QALY is a standard measurement for health technology assessment. The Ministry of Labor, Health, and Welfare (2016) recommends QALY for evaluating cost effectiveness of medical treatments or services [21]. In this study, QALY data is assigned to patients based on the results of Hattori et al. (Table 2) [36]. The expected QALYs are discounted at 2% per year [20].

Results

Patient accessibility

The estimated number of AIS patients were 8,528, excluding 16 patients in the solitary island areas. Figure 1 shows the rates for patients transported to hospitals with endovascular thrombectomy within 3 hours (covered rate), and the detailed results (e.g. the number of patients in each time window, the covered rates) are shown in Table 3. Covered rates were 98.5% (8,397) for the current scenario, 99.0% (8,442) for the 60-minute scenario, and 99.1% (8,448) for the 90-minute scenario. The transport time of 178 and 248 patients would be shortened by the 60-minute and 90-minute scenario, respectively (these figures are obtained by

summing the number of patients whose transport time was shortened at each medical area (Table 3)). In 14 of the 21 secondary medical areas, covered rate was 100% in the current scenario. Currently, approximately 7.6% of the patients are transported to hub hospitals within 1 hour in the Kamikawahokubu medical area. The rate can increase to 85% with the drive and retrieve system. In Emmon, Kitaoshimahiyama, and Kamikawahokubu areas, the cover rates would be 100% in the 60-minute scenario. In Rumoi area, the covered rate was 87% in the current scenario. The number increases to 93% in the 60-minute scenario, and 100% in the 90-minute scenario. Soya has the lowest covered rate in the current scenario (1%). Although the rate would increase to 25% and 26% in the 60-minute and 90-minute scenarios, respectively, rt-PA and endovascular thrombectomy would still not be accessible to a large number of patients. In Hidaka and Nemuro, 5% and 2% of patients would currently not be transported to hub hospitals within 3 hours, and the rate would not change even in the 90-minute scenario, respectively.

Table 3. The number of patients transported in each time window in each medical area

Secondary medical area	Scenario	Transport Time Window					Cover Rate
		Total	0-1 hour	1-2 hour	2-3 hour	over 3 hours

Per-patient medical and nursing care costs

When calculated considering treatment eligibility and the transfer time windows, the per-patient medical and nursing care costs for patients treated with rt-PA and endovascular thrombectomy were \$36,323 in the 0–1 hour window, \$38,139 in the 1–2 hour window, \$39,774 in the 2–3 hour window, and \$55,506 without these treatments. After adjusting these costs with the implementation rate of these treatments, the expected per-patient costs at each transport time window were \$51,852 in the 0–1hour window, \$52,159 in the 1–2 hour window, \$52,436 in the 2–3 hour window, and \$55,506 in the over 3 hour window.

Cost-effectiveness of the drive and retrieve system

ICER after implementing the drive and retrieve system was calculated from the results of patient transport time, per-patient costs, and QALYs for each transport time window. The ICER was dominant, both in the 60-minute and 90-minute scenarios. QALY gain was 7.0 in the 60-minute scenario, and 8.13 in the 90-minute scenario. The results showed cost reduction of \$213,190 in the 60-minute scenario (Figure 2) and \$247,272 in the 90-minute scenario (Figure 3). Figure 2 shows the cost reduction in each secondary medical area achieved in the 60-minute scenario. Cost reduction is the highest in Soya (\$70,433), followed by Emmon (\$46,425), Kamikawahokubu (\$34,232), and Rumoi (\$18,067) in the 60-minute scenario. The reduction for these medical areas accounted for approximately 79% of the reduction in the whole Hokkaido. Figure 3 shows the cost reduction for each secondary medical area achieved in the 90-minute scenario. In 15 of the 21 medical areas, no change was observed between the results in 60-minute and 90-minute scenarios. In the 90-minute scenario, Soya area has the largest cost reduction (\$75,149), followed by Emmon (\$52,489), Rumoi (\$35,033), and Kamikawahokubu medical areas (\$34,232). Figure 4 shows the per-patient cost reduction. Expected per-patient cost reduction was the highest when the drive and retrieve system was applied to patients in Soya (\$3,062 per case), followed by Emmon (\$1,934 per case), Rumoi (\$1,807 per case), and Kitaoshimahiyama (\$1,296 per case).

Discussion

The patients in this study were generated based on the incidence and the actual population distribution in each 1 km² mesh in Hokkaido. Therefore, this distribution is likely to reflect the actual patient distribution. The covered rate was 98.5% in the current system, which indicates that a large number of patients can be

A Cost-effectiveness Simulation of Drive and Retrieve System in Hokkaido

eligible for rt-PA and endovascular thrombectomy, especially in the urban areas such as Sapporo, Kamikawachubu, and Minamihiyama, even in the current scenario. Soya had the lowest rate (1%), followed by Rumoi (86%), and the other 5 areas (Table 3). These medical areas do not have Spoke hospitals. The results indicate that regional disparity exists in accessibility of patients to these treatments, which supports previous studies [17], and corporation for AIS treatments among secondary medical areas is of importance to deliver more equal and efficient treatments. By implementing a 60-minute drive and retrieve system, the covered rate in Hokkaido would increase to 99.0%. 178 and 248 patients would benefit from the system by being transported in a shorter time window (Table 3). Therefore, the drive and retrieve system can increase equality in access to treatment for ischemic stroke patients, which is can be achieved using existing medical resources. The cover rate would increase from 1% to 25% in Soya, 89% to 100% in Emmon, 87% to 93% in Rumoi, and 96% to 100% in Kitaoshimahiyama. The results indicate that the drive and retrieve system within 60-minute drive distance is effective in these medical areas. In Kamikawahokubu, the rate of patients transported in the 0–1 hour time window would increase from 7.6% to 85%. Patients in this medical area can benefit from an early start of treatment. In Rumoi, the covered rates were 87%, 93%, and 100% under the 3 scenarios. The 90-minute scenario would help in providing more equal treatment in Rumoi area.

Per-patient expected costs were cheaper, and per-patient expected QALYs were higher with shorter time windows. This is attributed to better outcomes due to an early start of treatment, which results in less medical and nursing care costs. The amount of QALY gained was not substantial because in Hokkaido, a

A Cost-effectiveness Simulation of Drive and Retrieve System in Hokkaido

large part of population can be transported within 3 hours even in the current scenario. However, since the

ICER from implementing the drive and retrieve system was dominant, the system can be a solution to

enhance equality and cost-effectiveness of treatments for patients with AIS.

There were cost reduction effects of the drive and retrieve system. The analysis revealed that cost reduction

was high in Soya, Emmon, Rumoi, and Kamikawahokubu. As mentioned above, patients in these medical

areas can expect better outcomes through transportation in a shorter time window, and the increase in cover

rates. Since the number of neurointerventionists is limited, it is necessary to prioritize the allocation of

new human resources in these medical areas.

Per-patient cost reduction is the highest in Soya, followed by Emmon, Rumoi, and Kitaoshimahiyama.

More and more patients became eligible for rt-PA and endovascular thrombectomy with this system in

these areas. Since high effectiveness of rt-PA and endovascular thrombectomy have been reported [4,5], it

is desirable that these treatments are given to as many patients as possible. Even though the increase in the

number of patients covered by the system is not substantial, it would be of great importance in providing

more equal and cost-effective treatment for patients with ischemic stroke in Hokkaido. Further cost

analysis is required from the hospital perspective.

However, this study has several limitations. First, the period of QALY and cost analyses is 3 years due to

lack of data. Post-stroke disability is likely to last for a lifetime [32]. Therefore, lifetime analyses with

detailed data will give a better assessment of the effects of the drive and retrieve system. Second, due to

lack of data, the implementation rate of rt-PA and endovascular thrombectomy is constantly set at 16.9%.

A Cost-effectiveness Simulation of Drive and Retrieve System in Hokkaido

In a clinical condition, it is possible that the rate varies with transport time, and the implementation rate can improve and change over time. Third, although the results of this study revealed the possible cost reduction brought by implementing the drive and retrieve system, our analysis did not contain public costs to maintain the system that may arise if the system is implemented as a policy (e.g. subsidy for hospitals that manage the system). Lastly, further research is required to apply the drive and retrieve system in a wider area, after considering the availability of the neurointerventionists.

Conclusion

In this study, the effects of the drive and retrieve system in Hokkaido on patient accessibility to rt-PA and endovascular thrombectomy was analyzed using GIS; and the cost effectiveness of the system was assessed with ICER from the public perspective as a primary outcome, in order to provide data for effective management of ischemic stroke treatments. The results indicated that there were regional disparities in patient accessibility to these treatments. It is possible to reduce disparities using the drive and retrieve system. The cost-effectiveness analysis revealed that the ICER was dominant after implementing this system, and cost reduction would be expected. Therefore, this system can be a solution to achieve more equal and cost-effective treatments. Additionally, the results showed that cost reductions were high in Soya, Emmon, Rumoi, and Kamikawahokubu medical areas. Further analysis from hospital perspective is required to clarify whether the system is cost-effective for involved hospitals.

Figure Legends

Figure1: Covered rate in each scenario

Figure Legend: The rates of patients whose transport time are within 3 hours (Cover rate) in each scenario

((a) the current scenario, (b) the 60-minute scenario, and (c) the 90-minute scenario) are visualized in Figure

1. The results showed that 100% cover rate was achieved in 14 of 21 areas in the current scenario. 100% cover rate would be achieved in the 60-minute drive scenario in Emmon, Kitahitamaoshima, Kamikawahokubu medical areas, in the 90-minutedrive scenario in Rumoi area. In Hidaka and Nemuro medical areas, the cover rates would not change even by implementing the drive and retrieve system. In Soya are, the cover rate would still be 26% even with the drive and retrieve system.

Figure2: The cost reduction in each secondary medical area in 60-minute scenario (\$US)

Figure Legend: Figure 2 shows the cost reduction in each of the secondary medical areas achieved by implementing the 60-minute drive scenario. The result showed that the total cost reduction was \$213,190. Cost reduction is the highest in Soya (\$70,433), followed by Emmon (\$46,425), Kamikawahokubu (\$34,232), and Rumoi (\$18,067).

A Cost-effectiveness Simulation of Drive and Retrieve System in Hokkaido

Figure3: The cost reduction in each secondary medical area in 90-minute scenario (\$US)

Figure Legend: Figure 3 shows the cost reduction in each of the secondary medical areas achieved in the 90-minute scenario. The result showed that the total cost reduction was \$247,272. Soya area has the largest cost reduction (\$75,149), followed by Emmon (\$52,489), Rumoi (\$35,033), and Kamikawahokubu medical areas (\$34,232).

Figure4: the cost reduction gained per 60-minute drive and retrieve system (\$US)

Figure Legend: Figure 4 shows the results of per-patient cost reduction in each secondary medical area, which is calculated by deriving the total cost reduction by the number of patients whose transport time are shorten by 60-minute drive scenario. Per-patient cost reduction was largest in Soya area (\$3,062 per case), followed by Emmon area (\$1,934), Rumoi (\$1,807), Kitahiyamaoshima (\$1,296).
