ABSTRACT

Recent studies reported multiscale structure in tough and self-healing hydrogels containing physical associations. For example, a type of tough and self-healing hydrogels from charged balanced polyampholytes (PA) have a meso-scale bicontinuous double network structure with structural length around 400 nm. This meso-scale network structure plays an essential role in the multistep rupture process, which leads to the high toughness of PA hydrogels. In this work, by using an osmotic stress method, we symmetrically studied how the relative strength of soft and hard networks and the strength of ionic bonds influence the property of PA gels. We found that, increasing osmotic stress of the bath solution triggers the structure transition from bicontinuous double network structure to a homogeneous structure, which drives the concurrently opaque-transparent transition in optical property,

and viscoelastic-glassy transition in mechanical behavior. The gels around the structural transition point were found to possess both high toughness (fracture energy of 7200 J m⁻²) and high stiffness (Young's modulus of 12.9 MPa), which is a synergy of soft network and hard network of the bicontinuous structure. Our work not only provides an approach to tune the structure and property of physical hydrogels through tuning physical association, but also gives a demo to investigate their relationships, yet another step forward, gives inspiration to design new type of tough and self-healing materials around the structural transition point.

INTRODUCTION

Hydrogels composed of three-dimensional polymer network and abundance of water have attracted considerable attention due to their prime importance in many fields, such like stimuli response¹⁻³, drug delivery^{4,5} and tissue engineering⁶. However, the applications of hydrogels are usually restricted seriously by their mechanical weakness⁷⁻⁹. Since 2000, substantial efforts have been devoted to develop strong and tough hydrogels¹⁰⁻¹⁴, among them the double-network (DN) gels, by incorporating a stiff and brittle network as sacrificial covalent bonds into a soft and ductile network matrix, stands out as one of the most tough hydrogels¹⁵⁻¹⁹. Inspired by the sacrificial bond concept used in DN gels, various tough and strong physical hydrogels with partially or even completely self-healing ability were successfully developed, by using reversible physical bonds as sacrificial bonds²⁰⁻²⁵. For example, the physical hydrogels from polyampholytes (PA gels) with ionic interactions as sacrificial bonds, possess not only high toughness and high fatigue resistance, but also 100% self-recovery and a very broad relaxation spectrum.^{21,26,27}

Despite great success on creating tough and self-healing hydrogels through reversible physical bonds, the fundamental basis, the structure and the toughening mechanism of these gels, remains poorly understood. These physical hydrogels have been described by a simple dichotomic molecular picture of the elastic network crosslinked by weak bonds and strong bonds, whereupon the weak bonds can break to dissipate energy and reform to impart self-healing, and strong bonds can maintain the integrity of the gels over a much longer timescale. Recent studies reported the large scale heterogeneous structure in these gels with structural length in tens or hundreds nanometers scale, like PA system in water²¹, polyacrylamide system in a mixture of good and poor solvents²⁸ or poly(N-isopropylacrylamide) system above the critical temperature²⁹, suggesting that the dichotomic molecular picture is too oversimplified. Especially, our recent study by combining atomic force microscopy (AFM) and time-resolved small-angle X-ray scattering (SAXS) suggests that the PA hydrogels have a multiscale structure, and the toughening results from a synergistic effect involving multiscale energy dissipation.³⁰

PA gels has a hierarchical structure of several length scale: at the monomer scale, the positive and negative charges associate to form ionic interactions; at the nanoscale, the charged chains aggregate into soft and hard regions, which differ in modulus and polymer density; in the mesoscale, the soft and hard regions form a bicontinuous double network structure. This multiscale structure leads a multiscale energy dissipation during deformation.³⁰ Upon loading, the microscopic deformation of bicontinuous networks is perfectly affine up to a quite large macroscopic uniaxial tensile deformation range, followed by a wide nonaffine deformation range. In affine deformation regime, the breaking of ionic

bonds in monomeric scale occurs to induce unfolding of the globular chains, permitting a large mechanical hysteresis, but the samples are fully self-recoverable due to self-healing effect of the dynamic physical bonds. In the nonaffine deformation regime, the hard network ruptures due to the high stiffness and the samples exhibit permanent softening while their shape are fully recoverable, due to elasticity of the soft network. In nonaffine regime, the soft network effectively transfers stress and reduces stress concentration, preventing the catastrophic propagation of hard network rupture. Finally, the rupturing of soft network leads to the global failure of sample. Such meso-scale double network structure prevents the catastrophic propagation of hard network rupture, leading to a large deformability of the materials before global failure. This multi-scale rupture process dissipates a significant amount of energy to give a high toughness of gels.

Given the above picture, the mechanical properties of the PA gels should be correlated to the strength of ionic interactions, and the relative strength of soft and hard networks. The former is relevant for the energy dissipation and viscoelasticity of gels. The latter is relevant for stress transfer and reduction of stress concentration when the hard network rupturing. In this work, we aim to study how the strength of ionic interaction, and the relative strength of soft and hard networks influence the properties of PA hydrogels. For this purpose, an osmotic stress method is adopted by using the neutral and biocompatible poly(ethylene glycol) (PEG) solutions to tune the osmotic pressure of the bath solution^{31,32}. We start with PA gel equilibrated in pure water. The bicontinuous mesoscale double network structure formed in PA gels is the result of thermo equilibrium in water. When the bath solution is changed from water to PEG solution, an osmotic pressure is exerted on the PA gel

from the solution. As a result, the gel is dehydrated to reach a new equilibrium state. As the ionic associative energy increases with polymer volume fraction^{21,33}, the strength of ionic interaction is tuned by tuning osmotic stress without changing the topological chain structure of gels. Since the dehydration abilities of the dense, hard network region and the sparse, soft network region are different, the relative strength of the two networks is expected to change with the PEG concentration.

In this work, the effects of relative strength of soft and hard networks, and the strength of ionic interaction on mechanical property of PA hydrogels were systematically studied with the osmotic stress method. Our results show that, by increasing osmotic stress of the bath solution, the contrast between soft and hard networks decreases and eventually disappears, that is, the gel transforms from heterogeneous structure to homogeneous structure. This heterogeneous-homogeneous transition in structure is concomitant with an opaque-transparent transition in optical property. At a given observation time, the gels with a heterogeneous structure is ductile and with a homogeneous structure become glassy, while the gels near the structural transition point possess the maximum toughness. This maximum toughness is a synergy of increased strength of ionic bonds to dissipate energy and reduced deformability due to structural homogenization.

EXPERIMENTS

Materials. All the materials, including anionic monomer p-styrenesulfonate (NaSS), cationic monomer 3-(methacryloylamino) propyl-trimethylammonium chloride (MPTC), photoinitiator α -ketoglutaric acid (α -keto), and PEG with weight-average molecular weight

M_w of 2×10^4 g/mol were purchased from Wako Pure Chemical Industries, Ltd (Japan) and used as received. Deionized water was used in all of the experiments.

Synthesis of PA hydrogels. The charge balanced P(NaSS-co-MPTC) hydrogels were synthesized with a one-step random copolymerization procedure, which has been described in detail in our previous work.^{21,34} In brief, a mixed aqueous solution containing NaSS, MPTC and α -keto was injected into a sandwich like sample cell (thickness: 2 mm) and irradiated with UV light (wavelength of 365 nm) for 11 hours under argon atmosphere. The total monomer concentration C_m is 2.1 M, the molar ratio of NaSS : MPTC is 0.525 : 0.475, and the concentration of α -keto is 0.25 mol% relative to C_m . The PA synthesized at this formulation has balanced charges. After polymerization, the obtained gels (as-prepared gels) were immersed into large amount of water longer than one week at room temperature to remove counterions and residual chemicals and to reach equilibrium. In water, the sample shrank isotropically, and the thickness changed from 2.0 mm to about 1.9 mm.

Preparation of PA hydrogels with different polymer volume fraction. The osmotic pressure of the bath solution is tuned roughly in a range from 0 to 10 MPa by using PEG aqueous solutions with weight percentage from 0 wt% to 60 wt%^{31,32}. There is no preferential interaction between PEG and PA, and the molecular weight of PEG is large enough that the diffusion of PEG into the PA gel is negligible. The water equilibrated hydrogels were immersed into various PEG solutions to re-equilibrate for one week at room temperature. After re-equilibration, the water weight percentage of gel (or water content) c_w was measured by the weight change upon drying at 120 °C with an electronic moisture balance device (Figure S1a, Supporting Information). The polymer volume fraction (ϕ_p) of

hydrogels was determined by the equation $\phi_p^{-1} = 1 + \left(\frac{c_w}{1-c_w}\right) \frac{\rho_p}{\rho_w}$, where $\rho_p = 1.19 \pm 0.02 \text{ g cm}^{-3}$ and $\rho_w = 0.98 \text{ g cm}^{-3}$ are the density of PA and water at room temperature, respectively.³⁵

Optical transmittance test. The transmittance of the gels was characterized by a Shimadzu UV spectrophotometer with wavelength from 500 to 700 nm at room temperature of 24 °C (Figure S1b, Supporting Information). The experiment was conducted in PEO solution at room temperature. PEG solutions without gel were also measured as background to correct the transmittance of gels.

X-ray scattering measurement. The SAXS measurement was performed at BL16B beamline of Shanghai Synchrotron Radiation Facility (SSRF, China). The X-ray energy used was 10 keV and the distance between sample and detector was 5370 mm. A Mar 165 CCD detector (2048×2048 pixels with pixel size of 80 μm) was used to collect two-dimensional (2D) scattering patterns with data acquisition time of 20 s per frame. Ultra-small-angle X-ray scattering (USAXS) measurement was conducted at BL20XU beamline of Spring-8 (JASRI, Japan). The X-ray energy was 23 keV and the distance between sample and detector was 160.5 m. A Pilatus 100 K detector (487×195 pixels with pixel size of 172 μm) was used with data acquisition time of 60 s per frame. In all X-ray scattering measurements, gels were measured at room temperature and covered with Kapton film to prevent possible drying. SAXS and USAXS data were analyzed with Fit 2D software from European Synchrotron Radiation Facility³⁶ and corrected for detector spatial distortion, X-ray beam fluctuation and background scattering.

Rheology test. The rheological measurement was conducted with a parallel-plate geometry using an ARES-G2 rheometer (TA instruments, USA). A frequency sweep varied from 0.1 to 100 rad/s was performed with a constant strain of 0.1%. Disc-shape samples with a diameter of 15 mm and a thickness of 1.6-1.9 mm were adhered to the parallel plates with superglue and surround by PEG solution or paraffin oil during measurement. The frequency sweep experiments were conducted at different temperatures from 0 to 95 °C with per 8 °C a step. Before measurement, the sample was held at the pre-set temperature for 300 s to reach equilibrium, and the auto-strain function as well as manual gap adjustment were used to minimize compression on the sample.

Mechanical test. Two sets of uniaxial tensile tests were carried out, one is at room temperature, another is at high temperature (52 °C). The room temperature test was performed in an Instron 5965 tensile tester (Instron Co.), and the high temperature test was performed in a Tensilon RTC-1310A tester (Orientec Co.). Samples were cut into a dumbbell-like shape with the JIS K 6261-7 standard (12 mm in gauge length and 2 mm in width). The tensile speed was fixed at 100 mm/min, which gives a nominal strain rate of 0.14 s⁻¹. The nominal strain rate is defined as the ratio of stretch speed to gauge length. The stress σ is defined as the force divided by the initial cross-section area of sample and the Young's modulus E is calculated from the slop of initial linear region of stress-strain curve. The yielding stress σ_y and yielding strain ε_y are calculated from the point where the slop of stress-strain curve is zero. The fracture stress σ_b and fracture strain ε_b are defined as the point where breaking occurs. The work of extension at fracture W_{extf} is calculated from the area under the stress-strain plot up to fracture. A loading-unloading test was performed at room

temperature with the same sample size and stretch speed as uniaxial tensile test. The maximum strain of loading process was set as 3.0 and the unloading speed was the same as the loading speed. Single-edge notch test^{37,38} was performed at room temperature to obtain fracture energy. In the single-edge notch test, rectangular samples with length of 20 mm, width of 10 mm, and without notch or with notch length c of 1 mm were used. The stretch speed was 100 mm/min. The fracture energy Γ was estimated by the equation $\Gamma = 2 \frac{3}{\sqrt{\lambda_c}} c W(\lambda_c)$. Here $W(\lambda_c) = \int_1^{\lambda_c} \sigma_{\text{un-notched}} d\lambda$ is the stored energy density³⁷ of an un-notched sample which can be estimated from the yellow area in Figure 6b or 6c, λ_c is the critical stretch ratio where crack propagation starts for the notched sample. In all mechanical measurements, samples were surrounded by PEG solution or paraffin oil to prevent possible drying. In each measurement, samples were measured at least three times to make an average and to calculate the error bar.

RESULTS AND DISCUSSION

Optical property.

The polyampholytes obtained in the as-prepared state are topologically entangled with each other and each polymer chain possesses oppositely charged ionic groups randomly distributed along the chain backbone. By dialysis of small counterions in pure water, ionic associations between opposite charges on the polymer chains, both intrachain and interchain, are switched on, forming a bicontinuous network structure, consisting a soft network (with low modulus) and a hard network (with high modulus), of ~100 nm in scale.³⁰ Figure 1a presents the pictures of PA hydrogels after re-equilibration in PEG solutions with different

PEG concentrations. The initial sizes of the gels are the same with a 10 mm diameter and a 1.9 mm thickness. After being immersed in PEG solution, the gels shrink by osmotic stress. The volume of gels decreases about 50%, while the corresponding polymer volume fraction ϕ_p increases about 120%, in the studied C_{PEG} ranging from 0 wt% to 60 wt% (Figure 1c). When C_{PEG} is smaller than 20 wt%, the gels are opaque, as demonstrated by the photo pictures in Figure 1a and by the almost zero transmittance in Figure 1b. While when C_{PEG} reaches 20 wt%, the gel becomes translucent, thus the background lattice becomes visible. The transparency of gels increases rapidly for $C_{\text{PEG}} > 20$ wt% and almost transparent gels can be obtained when C_{PEG} is larger than 40 wt%. This result shows that an opaque-transparent transition occurs in PA hydrogels by dehydration at C_{PEG} around 30 wt%, as shown by dotted red line in Figure 1b as a boundary. Similar opaque-transparent transition has also been reported in natural soft matter such as egg white or vitreous bodies of fish eyeballs during dehydration, in which strong physical associations exist.³⁹

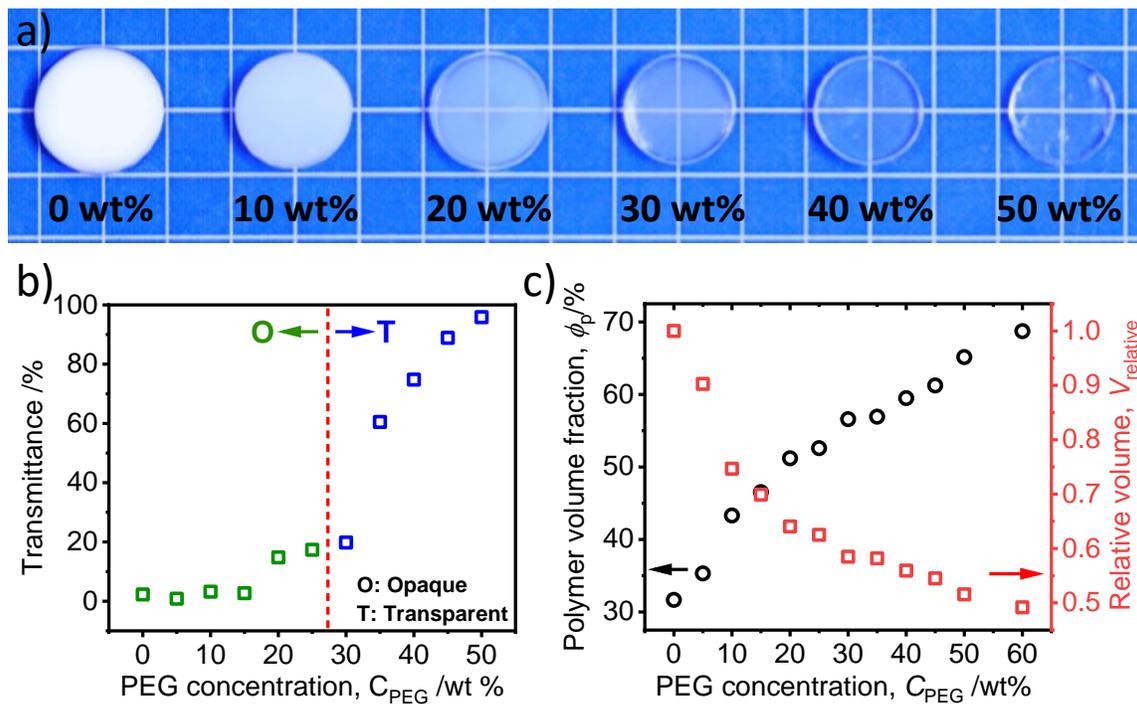

Figure 1. (a) Photographs of re-equilibrated PA hydrogels in different PEG aqueous solutions. The numbers in (a) are the PEG weight fraction of PEG aqueous solutions. The mesh size of background lattice is 5 mm. (b) The average transmittance of wavelength from 500 to 700 nm, and (c) the polymer volume fraction as well as the relative volume of PA hydrogels as a function of PEG concentration. The relative volume V_{relative} is defined as the volume of the gel in PEG solution compared to that in pure water.

Structural change.

To explore structural change behind the opaque-transparent transition in optical property, we combined USAXS and SAXS to study the structure of PA hydrogels at different ϕ_p . The gels with relatively low ϕ_p (in low C_{PEG} solutions) are opaque, suggesting the heterogeneity in structure with structural length around or above the wavelength of visible light. Our previous study has demonstrated that this heterogeneity is due to the formation of bicontinuous network structure.³⁰ Starting from the bicontinuous network structure, the opaque-transparent transition by increasing ϕ_p may be caused by two reasons. One is that,

the bicontinuous network structure transforms into homogeneous structure. Another is that, the structure of PA gel is still heterogeneous by increasing ϕ_p , but the structure length decreases to a value far smaller than the wavelength of visible light. The USAXS with q ranging from 0.0037 to 0.035 nm^{-1} can probe structure length from 1697 to 179 nm, which covers structure change in the scale of visible light region and beyond. While the SAXS with q ranging from 0.027 to 0.70 nm^{-1} can capture structural length from 233 to 9 nm, which is expected to verify whether the structure length of bicontinuous structure decrease to a much smaller size. Here $q = 4\pi\sin\theta/\lambda$ is the modulus of scattering vector, 2θ is the scattering angle and λ is the X-ray wavelength.

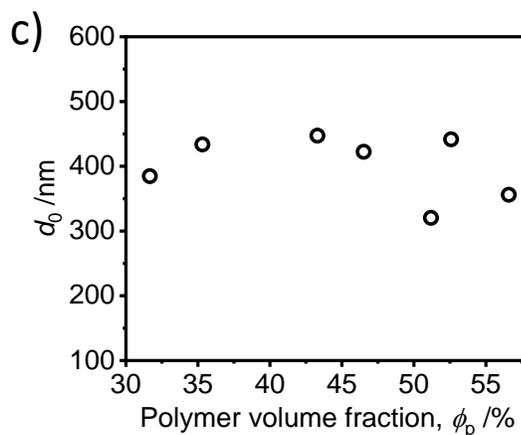

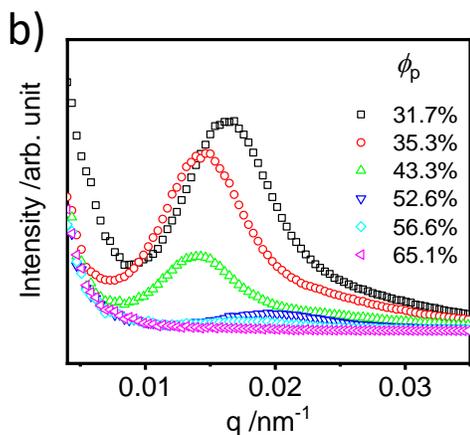

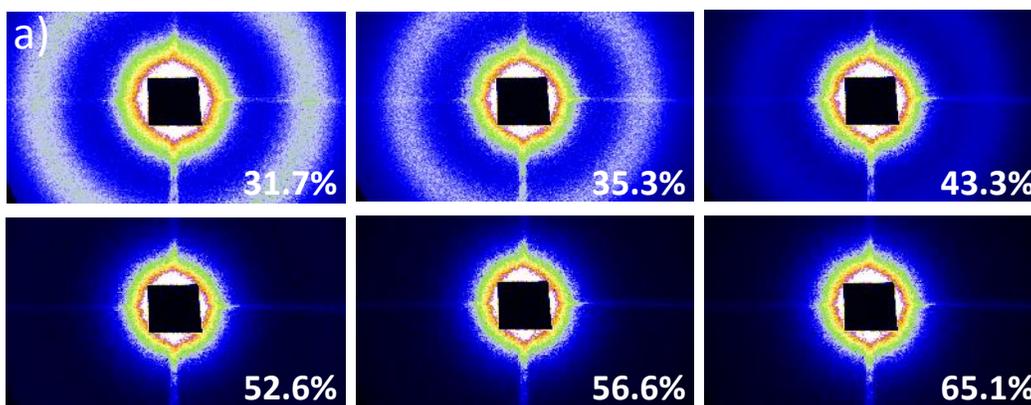

Figure 2. (a) 2D USAXS patterns of PA hydrogels at different polymer volume fraction ϕ_p and (b) the corresponding 1D intensity profiles. (c) The characteristic structural length d_0 as a function of polymer volume fraction ϕ_p .

Figure 2a reports the 2D USAXS pattern of PA gels at different ϕ_p . For $\phi_p \leq 52.6\%$, an isotropic pattern with a circular scattering ring appears, demonstrating the heterogeneous structure of gels. Note that the streak scattering around beam stop in 2D USAXS patterns is due to the background scattering of beamline. The scattering ring in 2D pattern gives rise to a correlation peak between $q = 0.01$ and 0.02 nm^{-1} in the 1D scattering intensity profile (Figure 2b), corresponding to a characteristic structural length (the spacing between adjacent soft regions or adjacent hard regions) d_0 about 400 nm (Figure 2c) that accounts for the opaque appearance of gels, in consistent with the previous report.³⁰ d_0 is calculated from the equation $d_0 = 2\pi/q_{\text{peak}}$, where q_{peak} is the peak position in the 1D scattering intensity profile. The intensity of scattering ring in 2D pattern (Figure 2a) and the corresponding correlation peak in 1D profile (Figure 2b) decrease by increasing ϕ_p for $\phi_p \leq 52.6\%$, suggesting the degree of heterogeneity decrease with increasing ϕ_p , while the value of d_0 hardly changes with increasing ϕ_p (Figure 2c). When $\phi_p > 52.6\%$, no visible scattering ring can be observed in the 2D scattering pattern and typical amorphous scattering or very faint peak appears in the 1D scattering intensity profile, indicating the gels become homogeneous in the detectable structural length of USAXS.

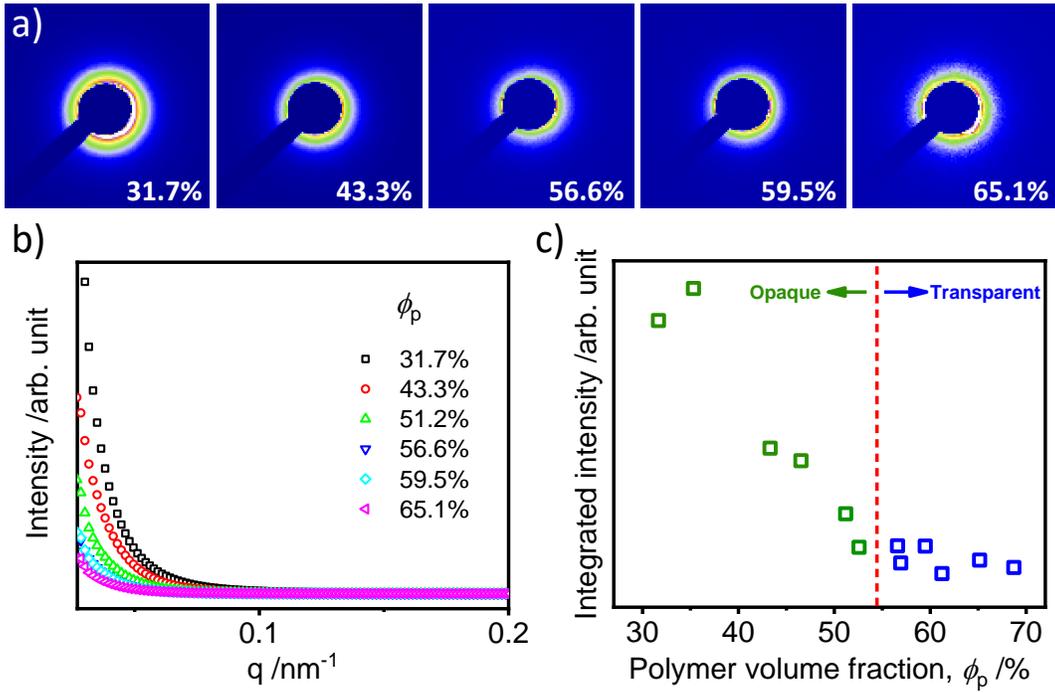

Figure 3. (a) 2D SAXS patterns of PA hydrogels at different polymer volume fraction ϕ_p and (b) the corresponding 1D scattering intensity profiles. (c) The integrated intensity as a function of ϕ_p . To highlight the intensity change in the 1D plot, data only at q ranging from 0.027 to 0.20 nm^{-1} are present in (b).

To examine the second possibility, i.e., whether the opaque-transparent transition is due to that the structure length of bicontinuous structure decreases to a much smaller size, SAXS was conducted and the obtained results are shown in Figure 3. In all studied ϕ_p , no scattering ring presents in the 2D SAXS patterns (Figure 3a) and no correlation peak arises in the 1D scattering intensity profiles (Figure 3b), demonstrating the absence of bicontinuous structure with structural length between 233 to 9 nm. Thus, the opaque-transparent transition is not due to the decrease in the structure length of bicontinuous structure. Meanwhile, the scattering intensity decreases by increasing ϕ_p in the whole q range investigated (Figure 3b), which is consistent with the results reported by Li et al.⁴⁰ To analyze the scattering intensity

change quantitatively, the 1D intensity profile was integrated in the whole studied q range and was plotted as a function of ϕ_p (Figure 3c). The scattering in SAXS can be considered as the high- q scattering regime of the USAXS (Figure S2, Supporting Information), which can be used to reflect the interface between soft and hard regions of bicontinuous structure.⁴¹ As shown in Figure 3c, the integrated intensity decays dramatically for $\phi_p \leq 52.6\%$, suggesting that the difference between two regions, i.e., the contrast, decreases by increasing ϕ_p , in agreement with USAXS results. Then the integrated intensity reaches a plateau, further demonstrating that the structure of PA become homogeneous for $\phi_p > 52.6\%$.

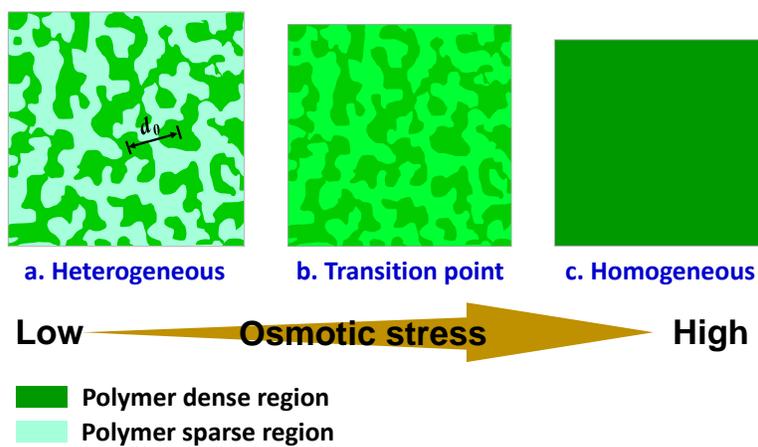

Figure 4. Schematic of structure evolution of PA hydrogels by changing osmotic stress from low to high.

Combing USAXS and SAXS results, one safe conclusion can be drawn is that, the bicontinuous structure with d_0 around 400 nm of PA gels transforms into a homogeneous structure by increasing ϕ_p (Figure 4). The boundary defined by heterogeneous-homogeneous transition in structure corresponds to the boundary defined by opaque-transparent transition in optical property exactly, suggesting that the heterogeneous-homogeneous transition is the

structural origin of the transmittance change in optical behavior. The gel starts with a bicontinuous network structure (Figure 4a), increasing the osmotic stress of PEG solution leads to the condensation of polymer. According to our previous work, the Young's modulus of the soft network and the hard network are 0.3 MPa and 1.9 MPa, respectively, measured by atomic force microscopy with a scan rate of 0.5 kHz.³⁰ Due to the difference in stiffness, the polymers in soft network (polymer sparse region) is much easier to condense than that of hard network (polymer dense region) under osmotic stress. Thereby the contrast between soft and hard networks decreases with increasing osmotic stress, as demonstrated by the USAXS results in Figure 2 and the SAXS results in Figure 3. When the osmotic stress or ϕ_p is larger a threshold ($\phi_p = 52.6\%$ for PA in this work), the “polymer sparse region” becomes dense enough as “polymer dense region” to form a homogeneous structure (Figure 4c). Here one question needs to explain is that why d_0 seems do not change with ϕ_p for $\phi_p \leq 52.6\%$ (Figure 2c). Assuming the bicontinuous structure undergoes homogeneous deformation during dehydration, d_0 should be proportional to $1/(\phi_p^{1/3})$. An increase in polymer volume fraction from 31.7% to 52.6% only lead to 15% reduction in d_0 , which may be smeared by the deviation of different samples.

Viscoelastic-glassy transition.

The relationship between structure and mechanical property was investigated by performing uniaxial tensile test. As demonstrated by the rheological data in Figure S3 (Supporting Information) as well as in our previous work²¹, PA hydrogels with bicontinuous structure are strongly viscoelastic with a very broad dynamic relaxation spectra and the

mechanical property strongly depends on the imposed strain rate. Here a specific observation time or observation strain rate (nominal strain rate 0.14 s^{-1}) was chosen, which is the same as that in our previous work^{34,35}. Figure 5a presents tensile stress-strain curves at four selected polymer volume fraction ϕ_p at room temperature. For $\phi_p \leq 52.6 \%$, the PA hydrogels are tough and ductile. Taking sample with $\phi_p = 31.7 \%$ as an example, the Young's modulus E , fracture stress σ_b and fracture strain ε_b can reach 1.7 MPa, 1.9 MPa and 9.4, respectively. When $\phi_p > 52.6 \%$, the gels become glassy-like, manifesting with a clear yielding like in glassy⁴² or semicrystalline⁴³ polymers. After yielding, a stress plateau appears, followed by a stress upturn. Meanwhile, both the Young's modulus and fracture stress are significantly increased, accompanying with a decrease in fracture strain. The fracture strain decreases to 1.8 when $\phi_p = 65.1 \%$, which is rather brittle compared to the sample with $\phi_p = 31.7 \%$ ($\varepsilon_b = 9.4$). In our previous study³⁰, real time SAXS result suggests that the hard phase starts to rupture around a strain of 3, which is reasonably consistent with the fracture strain of homogeneous glassy samples at $\phi_p > 52.6 \%$.

The viscoelastic-glassy transition in tensile behavior is compared with the linear rheological behavior. The nominal strain rate $\dot{\varepsilon} = 0.14 \text{ s}^{-1}$ in tensile test corresponds to a frequency ω of 0.14 rad/s in rheology test. In case of gel with $\phi_p = 31.7\%$, the loss factor $\tan\delta$ is 0.74 at $\omega = 0.14 \text{ rad/s}$ and the storage modulus G' as well as loss modulus G'' are strongly frequency dependent around 0.14 rad/s (Figure S3a, Supporting Information). Thus, this sample is observed in its highly viscoelastic regime. While in case of gel with $\phi_p = 65.1\%$, $\tan\delta$ is only 0.15 at $\omega = 0.14 \text{ rad/s}$, and G' has very weak and G'' has almost no

frequency dependency around 0.14 rad/s (Figure S3b, Supporting Information). This is the typical rheological behavior of glassy polymers, which explains well why this sample is glassy-like.

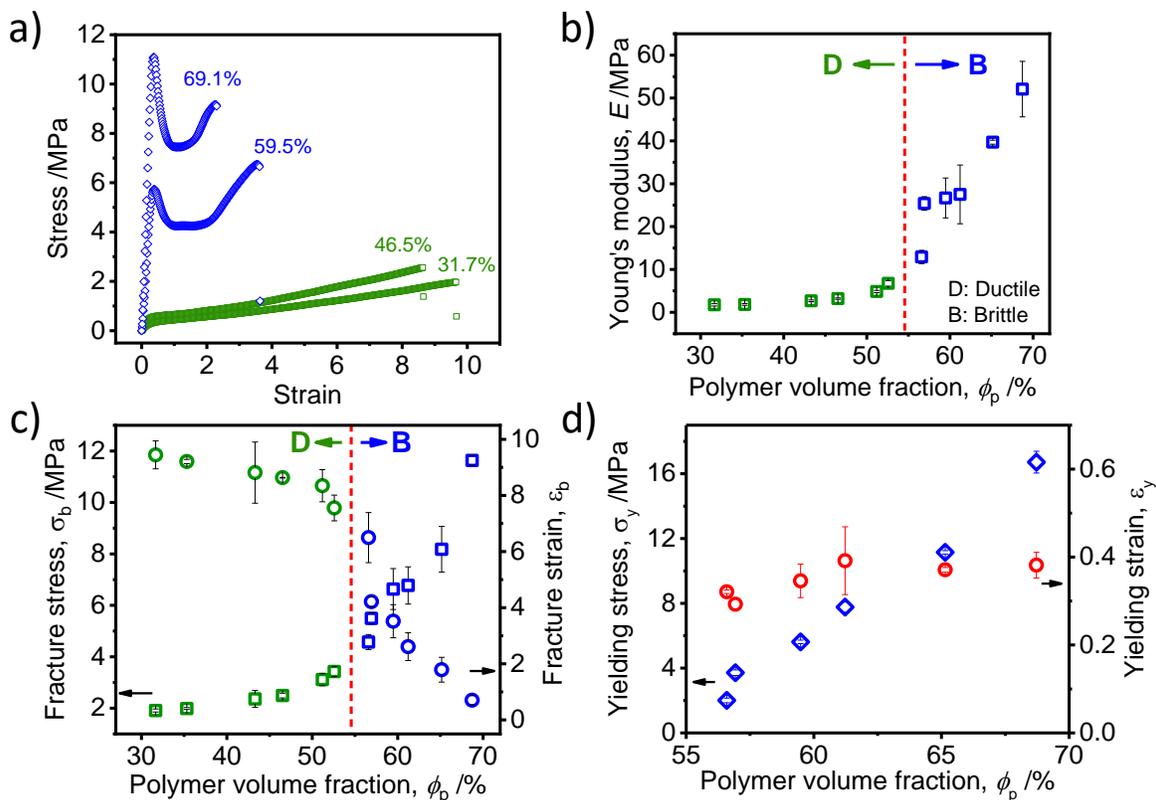

Figure 5. Tensile performance of the PA hydrogels. (a) Stress-strain curves of PA gels at different polymer volume fraction ϕ_p under uniaxial tensile test. (b-d) Dependence of (b) Young's modulus E , (c) fracture stress σ_b and fracture strain ϵ_b , as well as (d) yielding stress σ_y and yielding strain ϵ_y on ϕ_p . The tensile test was performed at a nominal strain rate 0.14 s^{-1} .

Figure 5b and 5c summarize the Young's modulus E , fracture stress σ_b and fracture strain ϵ_b at different polymer volume fraction ϕ_p . For $\phi_p \leq 52.6\%$, both E and σ_b show a gradual increase with ϕ_p , accompanying with a slightly decrease of ϵ_b . Once $\phi_p > 52.6\%$,

both E and σ_b increase sharply, while ε_b decreases drastically with ϕ_p . For example, varying ϕ_p from 31.7 to 52.6 % only leads to E changing from 1.7 to 6.7 MPa and ε_b changing from 9.4 to 7.6, while E reaches to 52.1 MPa and ε_b decreases to 0.7 when further increasing ϕ_p to 68.7 %. Obviously, the dependencies of stress-strain curves, E , σ_b , and ε_b on ϕ_p suggest that the mechanical behavior of PA hydrogels changes from viscoelastic to glassy-like by increasing ϕ_p , and the boundary of viscoelastic-glassy transition is at $\phi_p = 52.6$ %. Figure 5d summarizes the yielding stress σ_y and yielding strain ε_y as a function of ϕ_p , where σ_y increases from 2.0 to 16.7 MPa while ε_y has weak change by increasing ϕ_p .

The increase in polymer volume fraction ϕ_p cause two effects, one is the increase in the density of the original polymer chain and the other is the structure transformation from heterogeneous to homogeneous. For the former effect, by assuming the polymer density change is homogeneous during dehydration, the Young's modulus E , fracture stress σ_b , and fracture strain ε_b are related to ϕ_p by the following equations: $E = E^N \phi_p$, $\sigma_b = \sigma_b^N \phi_p^{2/3}$ and $\lambda_b = \lambda_b^N \phi_p^{1/3}$, where E^N , σ_b^N and λ_b^N are the values at the virtual reference state ($\phi_p = 1$).¹⁸ Here $\lambda_b = \varepsilon_b + 1$ is the fracture stretch ratio. To separate these two effects, we converted E , σ_b , and λ_b at various polymer volume fraction ϕ_p into the virtual reference state E^N , σ_b^N , and λ_b^N , respectively. The results are shown in Figure S4, Supporting Information. For $\phi_p \leq 52.6$ %, E^N and σ_b^N slightly increase, and λ_b^N slightly decreases with the increase in ϕ_p . While for $\phi_p > 52.6$ %, the E^N and σ_b^N increases, and λ_b^N decreases abruptly, demonstrating that the viscoelastic-glassy transition originated from the structure change rather than increase of polymer density. The yielding stress at the virtual reference state ($\phi_p = 1$) also

increases drastically with ϕ_p while the yielding deformation ratio at the reference state shows a constant value (Figure S5, Supporting Information). These results also indicate that in high ϕ_p region, the increase of ϕ_p leads to the PA gels to form glassy materials due to enhanced ionic interaction.

Toughness and self-healing.

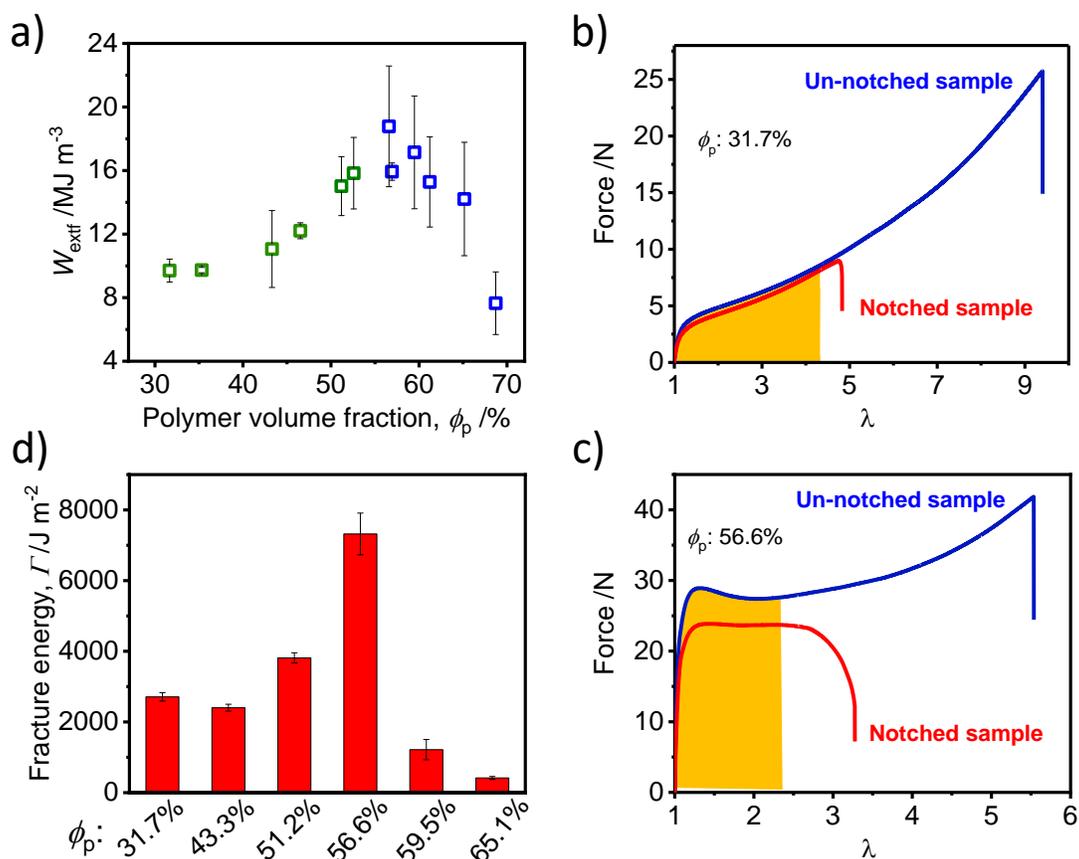

Figure 6. Toughness of PA hydrogels. (a) Work of extension at fracture W_{extf} at different ϕ_p . (b, c) Force-stretch ratio (λ) curves of notched and un-notched samples at $\phi_p = 31.7\%$ (b) and $\phi_p = 56.9\%$ (c). (d) Fracture energy Γ at various ϕ_p .

Based on the stress-strain curves in Figure 5, the work of extension at fracture W_{extf} can be calculated as a parameter to characterize the toughness of PA hydrogels (Figure 6a). W_{extf} firstly increases with ϕ_p and then decreases, giving a maximum around the structural transition point (heterogeneous-homogeneous transition). The maximum of W_{extf} is 18.8 MJ m^{-3} , almost twice of the reported most tough hydrogels of phase-separation polyacrylamide hydrogel²⁸. Single-edge notch test was also performed to evaluate the toughness of PA hydrogels following the previous studies³⁸. Figure 6b and 6c show typical force-stretch ratio curves for the un-notched and notched samples at $\phi_p = 31.7\%$ (bicontinuous structure) and $\phi_p = 56.6\%$ (around the structural transition point), respectively. The critical stretch ratio λ_c where crack propagation starts for the notched samples decreases with increasing ϕ_p . For example, λ_c for sample with $\phi_p = 31.7\%$ is 4.3 (Figure 6b), while decreases to 2.4 by increasing ϕ_p to 56.6 % (Figure 6c). The toughness represented by fracture energy Γ can be estimated from the yellow area in Figure 6b or 6c. The evolution of fracture energy Γ with ϕ_p is consistent with that of W_{extf} (Figure 6d). The fracture energy for sample with $\phi_p = 31.7\%$ is about 2700 J m^{-2} , in agreement with our previous results²¹, and demonstrates high toughness. The fracture energy of sample at maximum W_{extf} is about 7300 J m^{-2} , which is much larger than the tough double-network gels even with much higher modulus (12.9 MPa). The DN hydrogels known as extremely tough hydrogels possess fracture energy of 100~1000 J m^{-2} and modulus of 0.1~1.0 MPa.¹⁶ This result also indicates that, by tuning the structure through simple osmotic stress method, one can make PA hydrogels much stronger and tougher.

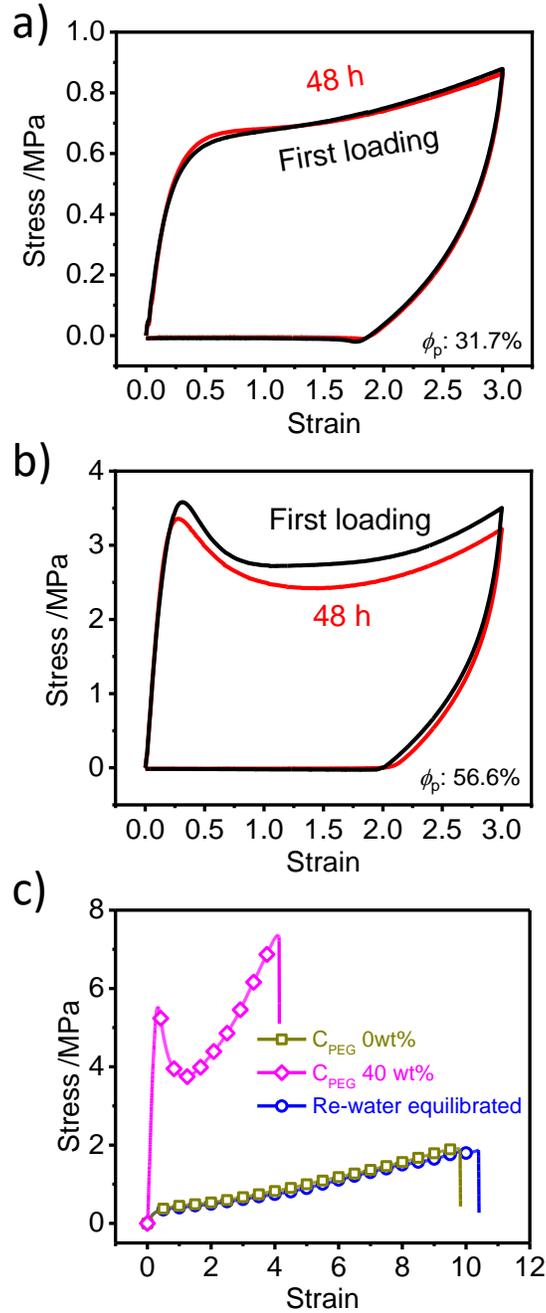

Figure 7. Loading and unloading uniaxial test of PA hydrogels with (a) $\phi_p = 31.7\%$ in water (0 wt% PEG solution) and (b) $\phi_p = 56.6\%$ in 30 wt% PEG solution. (c) Stress-strain curves of water-equilibrated sample, 40 wt% PEO solution-equilibrated sample ($\phi_p = 59.5\%$) as well as re-water-equilibrated sample. The stretch speed was 100 mm/min.

Since the broken physical ionic interactions are able to reform, the PA hydrogels possess self-recovery ability. As revealed in our previous study³⁰, the gel with bicontinuous structure ($\phi_p = 31.7\%$, in water) shows fully self-recovery before the internal fracture of the rigid phase that occurs above a strain of 3.0. Here we compare the self-recovery behaviors of two representative samples, the sample with bicontinuous structure ($\phi_p = 31.7\%$, in water) and the sample with homogeneous structure ($\phi_p = 56.6\%$ in 30 wt% PEG solution), which are shown by the cyclic loading-unloading stress-strain curves in Figure 7a and 7b, respectively. The maximum strain is set at 3.0, at which the sample with bicontinuous structure shows the full self-recovery. A large mechanical hysteresis is observed in both two samples, indicating large energy dissipation during deformation that is responsible for the high toughness of the hydrogels. The loading-unloading test was repeated after 48 h for those two samples without any thermal or chemical processing. In contrast to the sample with bicontinuous structure that shows fully recovery in its stress-strain curve, the homogeneous sample shows only 92% self-recovery in the hysteresis area although the residual strain fully disappears after the long waiting time (Figure 7b). The latter result indicates that some covalent bonds are broken in the case of the rigid homogeneous sample. It is interesting that although this sample shows a prominent yielding, during which the strong physical associations break, most of them recovered after enough waiting. This behavior is significantly different with the chemical DN gels, in which the yielding is due to the scission of covalent bonds in the first network¹⁶. The maximum strain to show full self-recovery decreases with the increase of the polymer fraction ϕ_p , indicating that the decrease of water

content freezes the dynamics of the ionic bonds and leads to partial damage of the covalent bonds in the case of PA gels above the viscoelastic-glassy transition point.

The structural transition induced by osmotic stress is reversible. When the hydrogels with a homogeneous structure was immersed into water to re-equilibrate, the homogeneous structure transform into bicontinuous structure and the gels recover to their initial sizes and mechanical properties. Figure 7c presents an example to demonstrate this property. The sample equilibrated in PEO solution ($C_{\text{PEG}} = 40 \text{ wt}\%$, $\phi_p = 59.5\%$) shows glassy like behavior with obvious yielding, high modulus, large fracture stress but small fracture strain. After immersing in water to re-equilibrate, this sample becomes viscoelastic and ductile, which is almost the same as the originally water-equilibrated sample ($C_{\text{PEG}} = 0 \text{ wt}\%$). This result demonstrates that the transition of mechanical property is due to structure change but without change of the topological chain network of gel.

Structure-property relationship.

Based on above results, we can make a brief summary here. (i) The osmotic stress leads to condensation of polymer and thus enhanced physical ionic interaction of PA hydrogels. (ii) USAXS and SAXS results suggest that the bicontinuous structure with structural length of about 400 nm transforms into homogeneous structure by increasing osmotic stress or polymer volume fraction ϕ_p . (iii) With increasing ϕ_p , optical results indicate an opaque-transparent transition, and mechanical results present a viscoelastic-glassy transition. (iv) The gels near the structural and mechanical transition point possess maximum toughness with work of extension at fracture of 18.8 MJ m^{-3} and fracture energy of 7200 J m^{-2} . (v) Both bicontinuous gel and homogeneous gel in this study show almost

fully self-recovery in a certain strain range even after obvious yielding and the structural transition induced by osmotic stress is reversible. It should be noted that the heterogeneous-homogeneous transition in structure corresponds to transitions in optical and mechanical properties exactly, suggesting the intrinsic correlation between structure and properties of PA hydrogels.

The structure of PA hydrogels is heterogeneous with local polymer dense region (hard region) and sparse region (soft region) for $\phi_p \leq 52.6\%$ (Figure 4a). Up to a relatively large deformation, the bicontinuous network shows a reversible affine deformation, during which nanoscale chain conformations change with ionic bond breaking in the two regions dissipating energy. At larger deformations, the bicontinuous network is highly stretched, and some parts of hard network start to rupture as they carry most of the stress, while the soft network can decrease stress concentration and transfer stress via shear. Such a meso-scale double network structure prevents the catastrophic propagation of hard phase rupture, leading to a large deformability of the gels before global failure. Consequently, the PA gels with bicontinuous structure are tough and highly viscoelastic.³⁰

When the osmotic stress or ϕ_p larger than a threshold ($\phi_p = 52.6\%$ for PA in this work), the polymer sparse region becomes dense enough as polymer dense region to form a homogeneous structure (Figure 4c). As a result, there is no soft network to transfer stress and decrease stress concentration. Thereby the sample is easy to fracture once microcracks generate, as demonstrated by the small fracture strain of the gels with a homogeneous structure (Figure 5c). At this stage, increasing ϕ_p leads to the homogeneous structure to form much stronger ionic interaction as crosslinking point, as the ionic interaction is polymer

concentration dependent according to electrostatic interaction theory.^{21,33} This explains why the Young's modulus and fracture stress increase sharply with ϕ_p (Figure 5).

The maximum toughness of PA hydrogels near the structural transition point is the result of two opposite effects. The increase of the ionic bond strength that relevant for the strength of gel and the decrease of the relative strength of soft network and hard network that relevant for deformability. For the bicontinuous structure gels (Figure 4a), the existence of soft network can effectively transfer stress and reduce stress concentration, endowing the gel a large deformability, during which the breaking of ionic bonds and the rupture of hard network dissipate energy. However, the strength of ionic bonds at this stage is relatively weak, meaning that less energy is dissipated by breaking ionic bonds during deformation. When the soft network becomes the same as the hard network by dehydration (the gel becomes homogeneous, Figure 4c), the stress-transferring and crack-stopping mechanisms disappear due the absence of soft network, resulting in a small deformability and thus low toughness of gels. While around the structural transition point (Figure 4b), the soft network is comparable, but “weaker” than the hard network. At this stage, the soft network still can transfer stress and reduce stress concentration to give a large deformability of the gels. At the same time, the ionic bonds are relatively strong to dissipate significant amount of energy. As a result, the gels around the structural transition point possess maximum toughness.

One may argue whether the sharp decrease in deformability is due to structure change from heterogeneous to homogeneous, or solely due to the modulus change by dehydrating gels into glassy-like state. To see the effect of heterogeneous structure, we compared the fracture strain of bicontinuous and homogeneous samples at the same modulus. The gel with

$\phi_p = 31.7\%$ was chosen to represent the bicontinuous sample, and the gel with $\phi_p = 59.5\%$ was chosen to represent the homogeneous sample. To compare their mechanical performance at the same modulus, the gel with $\phi_p = 31.7\%$ was tested at room temperature, while the gel with $\phi_p = 59.5\%$ was tested at $52\text{ }^\circ\text{C}$, at the same nominal strain rate of 0.14 s^{-1} . The ϕ_p of gel decreases slightly from 59.5% at room temperature to 56.5% at $52\text{ }^\circ\text{C}$ due to thermal expansion. Figure 8a shows the stress-strain curves of these two samples. The sample with homogeneous structure has a higher stress but lower extensibility than the sample with bicontinuous structure. Figure 8b shows the corresponding normalized Young's modulus and normalized fracture strain after removing polymer density effect with aforementioned method. Although their normalized Young's moduli are almost same, the gel with bicontinuous structure is more stretchable than the gel with homogeneous structure, suggesting that the bicontinuous structure results in delayed fracture due to the meso-scale double network effect.³⁰ It should be noted that a different batch of gels was used in this test, and this batch of samples were slightly more stretchable than those used in the previous tests of this work.

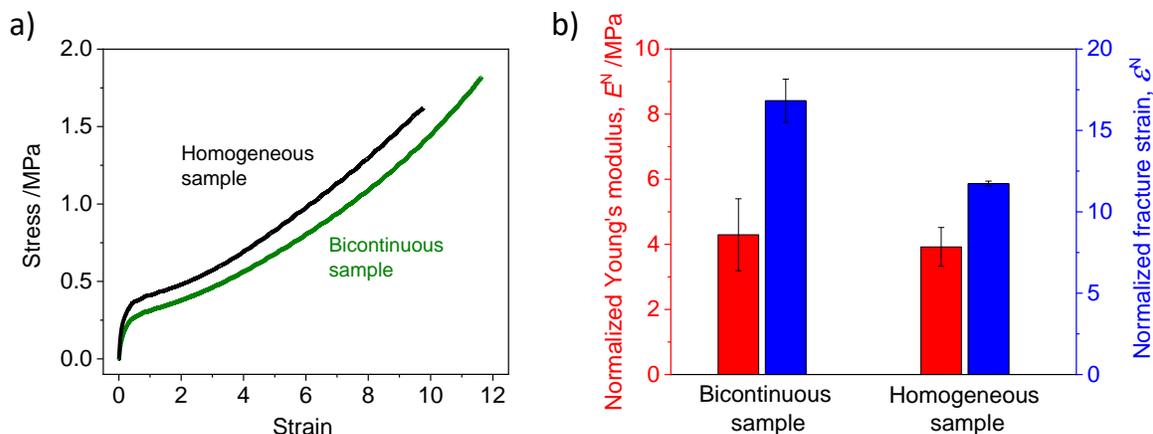

Figure 8. (a) Uniaxial tensile stress-strain curves of PA gels with bicontinuous structure ($\phi_p = 31.7\%$) measured at room temperature and with homogeneous structure ($\phi_p = 56.5\%$) measured at 52 °C. (b) The corresponding normalized Young's modulus E^N and normalized fracture strain ε^N . The test was performed at a nominal strain rate 0.14 s^{-1} .

CONCLUSION

In conclusion, by adopting osmotic stress method, we elucidated the missing link between structure and properties of PA hydrogels, and demonstrated that the optical and mechanical properties can be tuned in a wide range by changing ionic interaction. Specifically, 1) increasing osmotic stress of the bath solution triggers the dehydration of gel and resultant enhanced ionic interaction; 2) the mesoscale bicontinuous network structure transforms into homogeneous structure due to the difference in dehydration ability of the hard network and the soft network; 3) the heterogeneous-homogeneous transitions in structure drives concurrently opaque-transparent transition in optical property, and viscoelastic-glassy transition in mechanical property; 4) gels near the structural transition point was found to possess maximum toughness (fracture energy 7200 J m^{-2}), high stiffness (Young's modulus of 12.9 MPa) and self-recoverable ability (92% self-recovery); 5) the maximum toughness is due to the balance between enhanced ionic bond strength and decreased deformability by structure homogenization. This work not only establishes an approach to investigate the effect of structure-property relationship of physical hydrogels, but also gives inspiration to design tough and self-healing network materials around the structure transition point.
