ABSTRACT

Perovskite-type oxynitride BaTaO₂N has been attracting attention for its large dielectric constant that is almost independent of temperature by the measurements on its ceramics. Its dielectric characteristics are attributed to polar nano regions in the average cubic crystal structure. Polarization saturation to produce butterfly-like piezoresponse force microscopy (PFM) signal was observed on BaTaO₂N crystals in the present study. Reddish crystallites of BaTaO₂N up to

3.1 μm in size were grown using a BaCN_2 flux. Grain growth proceeded through the formation of a Ruddlesden-Popper type oxynitride from the reaction between BaTaO_2N powder and the molten BaCN_2 . Their electrical property was studied using PFM with special care due to the small size of crystals. They were found to be much highly insulating than its ceramics. Ferroelectricity with a complete phase inversion was observed on oxynitride perovskite crystal for the first time. Large coercivity of 50 to 60 V was observed in the measurement. Such ferroelectricity is ascribed to the polar nano regions induced by the polar linkages between *cis*-type TaO_4N_2 octahedra.

KEYWORDS (Oxynitride, Perovskite, Metal carbodiimide, Crystal growth, Ferroelectricity).

Introduction

Metal nitrides and oxynitrides have been attracting considerable attention because they are potentially useful for their optical, electrical, magnetic and mechanical properties.¹⁻⁷ Both SrTaO_2N and BaTaO_2N perovskites are also important as visible light-driven photocatalysts.⁸⁻¹⁰ They were also reported to show large relative dielectric constants with a small temperature dependence.¹¹ Their average crystal structures were assumed to be centrosymmetric tetragonal $I4/mcm$ ($a = 0.569411(7)$ nm, $c = 0.80658(2)$ nm) for SrTaO_2N and cubic $Pm-3m$ ($a = 0.41128(1)$ nm) for BaTaO_2N , based on powder neutron diffraction measurements.^{12,13} Some deviations from these centrosymmetric structures have been reported that suggest local symmetry breaking, based on analyses by transmission electron microscopy (TEM) and extended X-ray absorption fine structure (EXAFS) as well as neutron pair distribution functions as crystal structural supports for the occurrence of dielectric property.¹⁴⁻¹⁶ In 2011, two groups

independently reported a *cis*-type anisotropic local nitrogen configuration in TaO₄N₂ octahedra in SrTaO₂N based on powder neutron diffraction studies.^{17,18} These local *cis*-type units tend to align with random long-range orientation due to the similar lengths of the Ta-O and Ta-N bonds.^{19,20} Relaxor-type ferroelectric behavior was expected in first-principle studies on BaTaO₂N and SrTaO₂N assuming the *cis*-type configuration in their TaO₄N₂ octahedra. Two types of Ta-N-Ta-N helical chain motifs switch to each other, breaking the long-range ordering of anions while retaining the local *cis*-TaO₄N₂ anisotropic configuration.²¹ This disorder mechanism differs from that in typical solid solution relaxor oxide systems because the generation of compositional inhomogeneity is not necessary.^{21,22}

The electrical properties of these compounds have been investigated, both as ceramics and thin films, and they have been found to be significantly affected by anion contents in the products.^{6,23-28} Both SrTaO₂N and BaTaO₂N release a part of their nitrogen above 950 °C to change their compositions to SrTaO₂N_{0.7} and BaTaO₂N_{0.85}, respectively, even in a nitrogen atmosphere. The green-powder compacts of these materials change from orange or reddish-coloured insulators to black semiconductors during the high temperature sintering at 1400 °C due to the partial reduction of Ta⁵⁺.^{23,24,27,28} The nitrogen lost from these materials can be subsequently recovered by post-ammonolysis of as-sintered ceramics at approximately 950 to 1000 °C. However, this procedure was effective only at the surface of the dense samples because it was difficult for NH₃ to reach the interiors.²³⁻²⁶ Their original colors were completely recovered even in their interiors by the ammonolysis of the relatively porous ceramics. The SrTaO₂N ceramic with relative density (RD) of 84.0% showed relative dielectric constants $\epsilon_r \approx 300 - 450$ with loss $\tan\delta < 0.1$ and those of the BaTaO₂N ceramic with RD of 73.0% were $\epsilon_r \approx 290 - 620$ with $\tan\delta \approx 0.04 - 0.4$ in the temperature range from 25 – 150 °C.^{23,24} These ϵ_r values

Table 1. Growth conditions, appearances of the products and maximum grain sizes of BaTaO₂N crystals.

Product name	BaCN ₂ amount / mol%	Duration time at 910 °C / h	Cooling rate / °C h ⁻¹	Appearance after cooling	Maximum grain size / μm
As-prepared(a)	-	-	-	Reddish powder	0.2

(h)	46	24	1.8	Reddish solid	0.4

were significantly smaller than previously reported values of several thousands and the $\tan\delta$ were also much smaller than the previously reported values, which well exceeded 0.1.¹¹ These values of the ceramics exhibited minimal changes in temperature below 150 °C.^{23,24}

Piezoelectric behavior was reported on the outermost surface of dense sintered bodies of BaTaO₂N and SrTaO₂N with RD > 90% after their post-ammonolysis. Piezoresponse force microscopy (PFM) measurements were conducted on the thin ceramic surfaces in thickness of less than 10 μm scratched off from their bulks in the applied voltage range of ±10 V.^{25,26} Clear piezoresponse images were obtained over the range of 3 to 4 V for SrTaO₂N and 7 V for BaTaO₂N. Local hysteresis *P-E* loops were also acquired from thin specimens of a SrTaO₂N ceramic using a micron-sized Pt-deposited electrode over the applied voltage range of ±12 V.²⁵ However, its polarization could not be saturated because a serious current leakage appeared at higher voltage than ±8 V. This is presumably because a trace amount of electrically conductive

nature is present even after post-ammonolysis of nitrogen-deficient oxynitride ceramics.^{25,26} Highly-insulating and dense oxynitride samples are desired to elucidate the occurrence of polarization phase alternation by making it possible to apply high electrical voltage to the samples.

In other works, compressively strained SrTaO₂N thin films also showed ferroelectric behavior²⁹⁻³¹ below the bias voltage range of ± 8 V. It was observed only in very small domains with sizes of 10 – 100 nm and electrical leakage was observed during measurements as in the cases of the abovementioned ceramic specimens.^{25,26,29} The results of density functional theory (DFT) calculations suggested that SrTaO₂N film had *trans*-type anion ordering²⁹ and the deviation of anion distribution from *trans*- model was suggested in a Ca_{0.5}Sr_{0.5}TaO₂N thin film by assuming a change of its strain.³² The origin of the ferroelectricity in such inhomogeneous films is considered to be the compressive stress induced by the cell size mismatch between oxynitride films and oxide substrate, which cannot be determined as the intrinsic properties in oxynitride perovskites.²⁹⁻³¹

The formation of self-standing single crystals with an excellent electrical insulation is necessary to investigate the intrinsic electrical properties of oxynitride perovskites. Flux growth at relatively low temperatures is a potential means of growing crystals that might otherwise thermally decompose at high temperatures. However, there is very limited information available regarding the use of fluxes to produce nitrides and oxynitrides, except for the cases of the reactions of a Na flux with several metals and oxides to grow single crystals of Ba₃ZnN₂O, Ba₄GaN₃O and Sr₄GaN₃O.³³⁻³⁵ The formation of oxynitride perovskite crystals on the surfaces of single crystals of oxides such as Sr₂Ta₂O₇ and La₂Ti₂O₇ has also been reported.^{1,36,37} They are considered to be grown on these oxide single crystals in alkali metal halides or molybdates

fluxes but may not be self-standing. Additionally, some effects of KCl flux on the particle morphology of CaTaO_2N , SrTaO_2N , BaTaO_2N , and LaTaON_2 were reported.^{38,39} Submicron-sized cubic particles were observed, while crystals larger than several micron sizes are desirable for electrical property measurements. It should be noted that some contamination of potassium was reported in these oxynitride samples.³⁸ Ammonothermal method was employed to grow micron-sized oxynitride perovskite crystallites such as ABO_2N ($A = \text{Sr}, \text{Ba}$; $B = \text{Nb}, \text{Ta}$)⁴⁰, LnTaON_2 ($\text{Ln} = \text{La}, \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Gd}$)⁴¹, and LaNbON_2 .⁴² However, there is no reports on the electrical properties of such crystal products.

Recently, the stabilities of alkaline earth carbodiimides were investigated both experimentally and computationally to find out that tetragonal BaCN_2 melts at 910 °C.^{43,44} Molten BaCN_2 was used for the crystal growth of perovskite-type $\text{Sr}_{1-x}\text{Ba}_x\text{TaO}_2\text{N}$ ($x = 0.04 - 0.23$) under a nitrogen flow.⁴⁴ In this work, the original SrTaO_2N particles, which were round in shape and less than 100 nm in size, were partially dissolved in the BaCN_2 flux and crystals of the A-site substituted oxynitride perovskite $\text{Sr}_{1-x}\text{Ba}_x\text{TaO}_2\text{N}$ were grown as cubic grains with sizes up to 3.7 μm . The products had a compositional gradient from a Sr-rich interior to a Ba-rich exterior in their crystals.⁴⁴ It is therefore likely that compositionally homogeneous BaTaO_2N crystals can be obtained using a similar crystal growth technique starting with BaTaO_2N powder.

In the present study, small crystals of perovskite-type BaTaO_2N were grown in a BaCN_2 flux to several micron sizes for their electrical property measurements. The crystal growth mechanism was studied by microstructural analysis of the products using transmission electron microscopy (TEM). In addition, a ferroelectric nature was clearly detected in piezoresponse force microscopic (PFM) observation on the crystals in micron size. Secondary harmonic generation (SHG) was also observed to confirm the presence of a non-centrosymmetric structure consistent

with ferroelectricity. Herein, this ferroelectric behavior is discussed on the basis of polar nano regions (PNRs) in the BaTaO₂N crystal structure. This work represents the first-ever experimental demonstration to clarify the ferroelectricity of oxynitride perovskite crystals.

Experimental

Sample preparation

A reddish BaTaO₂N powder was obtained using the procedure described in the **Supporting Information**. A white BaCN₂ powder with a tetragonal crystal structure was prepared by the ammonolysis of BaCO₃ powder at 900 °C for 10 h.^{43,44} As-prepared BaTaO₂N powder was mixed with BaCN₂ in 17 – 67 mol% ratio for the crystal growth in a glove box filled with a dry nitrogen, so as to avoid oxidation or hydrolysis of the BaCN₂. Each resulting mixture was transferred into an alumina crucible and then enclosed in a container of tantalum sheets with thicknesses of approximately 0.1 mm (Nilaco, > 99%) in a nitrogen atmosphere to suppress the loss of the BaCN₂ flux due to its partial vaporization or decomposition above 910 °C.^{43,44}

The tantalum container was subsequently heated to 910 °C at a rate of 300 °C/h and held at that temperature for 30 min in an alumina tube furnace with a nitrogen flow of 30 mL/min. After heating, the sample was slowly cooled to 880 °C at a rate of 1.8 °C/h. In some trials, the cooling rate was increased to 300 °C/h to study the change in crystal size. The duration of the hold at 910 °C was also changed to 24 h to investigate the effect of flux loss above the melting point of BaCN₂, followed by cooling at a rate of 1.8 °C/h. The products were either reddish powder or solidified lumps embedding the grown crystallites, depending on the amount of BaCN₂ in the starting mixture. They were washed with 1 M nitric acid followed by distilled water to remove the soluble residue, consisting primarily of BaCN₂. A reddish powder was obtained after

filtration through filter paper with a pore size of less than 50 μm (Toyo Roshi K. K.). The preparation conditions, the product appearances after removal from the furnace, and the particle sizes of the washed final products are summarized in **Table 1**.

The crystalline phases in the products were identified using powder X-ray diffraction (XRD; Ultima IV, Rigaku) with Cu $K\alpha$ radiation over the 2θ range of 10 to 90° with a step size of 0.02° and a scan rate of $10^\circ/\text{min}$. Electron probe microanalysis (EPMA; JXA-8530F, JEOL) was conducted to determine the elemental compositions of the washed crystals having grain sizes larger than 2 μm .

The average molar ratio was determined to be $\text{Ba}:\text{Ta}:\text{O}:\text{N} = 23.0:22.1:37.0:17.9$, which roughly corresponds to the expected stoichiometric ratio of 1:1:2:1, confirming that the product was BaTaO_2N . The residual carbon content was less than the detection limit ($< 0.3 \text{ wt}\%$) of CHN combustion analysis (CE440, Exeter Analytical Inc.).

Observation and Characterization

A thin slice of the BaTaO_2N small crystals embedded in the solidified BaCN_2 (less than 100 nm thick) was prepared for TEM observations using a focused ion beam (FIB) of gallium ion (SMI 3050SE, Hitachi High-Technologies). A TEM instrument (Titan3 G2 60-300, FEI Company) equipped with a Cs-spherical aberration corrector was employed for microstructural observations of the crystals. In addition, high angle annular dark-field scanning TEM (HAADF-STEM) images were acquired using the same TEM instrument. The BaTaO_2N particle sizes and their surfaces were analyzed by scanning electron microscopy (SEM; JSM-6390 LVS, JEOL). The shapes of relatively large BaTaO_2N crystallites were observed with an optical microscope (VHX-2000, KEYENCE).

A spectroscopic analysis of secondary harmonic generation (SHG) by the BaTaO₂N small crystals was performed to elucidate the presence of a non-centrosymmetric structure. The excitation source was an acousto-optically Q-switched Nd:YAG laser (T40-X30S-106Q, Spectra Physics) with a 1064 nm wavelength, an average power of 0.6 W and a pulse width of 30 ns at a repetition rate of 4 kHz. The laser beam was focused by a lens with a 150 mm focal length on the surface of an aggregate of BaTaO₂N crystallites grown using 46 mol% BaCN₂ and a cooling rate of 1.8 °C/h (condition **(e)** in **Table 1**). This technique purposely used a low excitation power to avoid thermal decomposition of the BaTaO₂N during irradiation and to allow data accumulation over a long time span of 4 h.

The piezoelectricity of the BaTaO₂N small crystals prepared using condition **(e)** in **Table 1** was assessed using a PFM technique that is applicable to nano-sized areas in thin films avoiding some electrostatic effects to cause false detections of piezoresponse.⁴⁵⁻⁴⁸ Prior to the present analyses, some additional processes were performed as follows; Pt was deposited by sputtering as a top electrode on the surface of BaTaO₂N small crystals attached to a Cu substrate through an Au bottom electrode, to avoid any effects resulting from electrostatic forces.⁴⁶⁻⁴⁸ Further details regarding sample processing are described in the **Supporting Information**. Switching spectroscopy piezoresponse force microscope with DART technique (SS-PFM, ASYLUM MFP-3D, Oxford Instruments) was employed in an electrical field bias of up to ± 100 V through the probe coated with Ir metal (ASYELEC-01). SS-PFM was measured in a temperature range of up to 120 °C.

Results and Discussion

Characterization of the product obtained with 67 mol% BaCN₂

The crystalline phases of the grown product prepared using 67 mol% of BaCN₂ changed with its post-treatments as shown in **Figure 1**. The as-grown product was a reddish solid and its main phase was cubic BaTaO₂N perovskite with a lattice parameter $a = 0.4112(1)$ nm (**Figure 1(a)**). It was contaminated with a trace amount of the Ba-rich Ruddlesden-Popper (RP) type layered perovskite Ba₂TaO₃N along with another unidentified impurity. This Ba₂TaO₃N may have been

Figure 1. Powder XRD patterns of the BaTaO₂N grown with 67 mol% BaCN₂: **(a)** as-grown product, **(b)** product after exposure to air for 1 h, and **(c)** product after washing with nitric acid and water. Diamonds, arrows, inverted triangles, and question marks indicate diffractions for BaTaO₂N (ICSD 202763), Ba₂TaO₃N (JCPDS 47-1388), BaCO₃ (PDF 01-071-2394), and an unknown phase, respectively.

formed by the reaction of the BaTaO₂N perovskite with excess Ba supplied from the BaCN₂ flux. Oxygen could have been incorporated from the humidity or CO₂ adsorbed at the surface of BaTaO₂N and BaCN₂. The BaO-like intermediate reacted with BaTaO₂N to form the Ba₂TaO₃N impurity, which is reported to readily decompose reacting with oxygen and humidity.¹² The Ba₂TaO₃N impurity thus almost disappeared and formed another impurity of BaCO₃ during the reaction in air for 1 h (**Figure 1(b)**). Diffractions of the residual BaCN₂ were not observed in the XRD patterns of the material likely due to the low crystallinity after the heat treatment. Finally, the crystallinity of the BaTaO₂N was significantly improved after leaching of the as-grown product in nitric acid (**Figure 1(c)**). The full width at half maximum (FWHM) of the (321) diffraction peak for BaTaO₂N was found to significantly decrease from 0.31° to 0.22° by the leaching process, which produced highly crystalline BaTaO₂N. The lattice parameter ($a = 0.4111(1)$ nm) of the cubic BaTaO₂N perovskite was determined to be consistent with the literature value ($a = 0.41128$ nm).¹³ The cubic lattice also slightly shrank during leaching while the crystallinity was improved. These results suggest that structural defects present in the as-grown perovskite were removed by the nitric acid treatment, resulting in the formation of highly-crystalline BaTaO₂N. Generally, oxynitride perovskites are stable to nitric acid, but Ruddlesden-Popper phases (e. g. Sr₂TaO₃N and Ba₂TaO₃N) containing rock-salt type layers like SrO and BaO are decomposed by acid and humidity.^{12,50}

The microstructure of the product prepared with 67 mol% BaCN₂ before nitric acid leaching was assessed. Square-shaped BaTaO₂N crystals surrounded by solidified BaCN₂ flux are apparent in the TEM bright-field image of a thin slice of the as-grown product in **Figure 2(a)**. A selected area electron diffraction (SAED) pattern was obtained from the region indicated in this figure and the presence of cubic BaTaO₂N was confirmed by applying an incident electron beam

along the $\langle 110 \rangle$ direction, as shown in **Figure 2(b)**. No additional diffraction spots were observed. The lattice parameter was $a = 0.415(3)$ nm, which was in good agreement with that of the acid-washed powder sample shown in **Figure 1(c)** ($a = 0.4111(1)$ nm) within the experimental error. A high-magnification HAADF-STEM image (**Figure 2(c)**) shows cation ordering in a portion of the encircled area in **Figure 2(a)**. Ba and Ta atoms can be distinguished in this image because their brightness levels are different as a result of the effect of their different atomic numbers on the Z-contrast. Specifically, the Ta atoms appear slightly brighter than the Ba atoms. The atomic arrangement in **Figure 2(c)** is consistent with a cubic perovskite-type structure observed from the $\langle 110 \rangle$ direction.

The crystal lattice was not well developed in the areas around the crystal edges. The area encircled in **Figure 3(a)** was observed along the $\langle 111 \rangle$ zone axis and the atomic arrangement in the BaTaO₂N along this direction is clearly observed for the area labeled **1** at the bottom right of the higher-magnification image in **Figure 3(b)**. However, the arrangement is less clearly observed in the areas labeled **2** to **4**, which have different atomic orientations over ranges of approximately 3 to 10 nm. Fourier transformations of these images were performed using the Digital Micrograph software package (Gatan) for the areas labeled **1** to **4** in **Figure 3(b)** and the (01-1) lattice spacing was estimated from the lattice fringes indicated by the yellow arrows in this same figure. The average spacing in area **1** was determined to be 0.293 nm, which is consistent with the literature value of 0.291 nm.¹³ The average spacing estimated for area **3** was slightly larger (0.316 nm). For the area **4**, the crystal orientation could not be identified from the Fourier transform image. However, the average stripe spacing in area **4** was approximately 0.333 nm, which is larger than that for area **1**. One possible explanation is that the lattice fringes in area **4** correspond to the (004) planes of RP-type Ba₂TaO₃N with space group $I4/mmm$ together with a

$= 0.411508(3)$ nm and $c = 1.33778(1)$ nm.¹² The $c/4$ value was calculated to be 0.334 nm (JCPDS 47-1388). The area out of BaTaO₂N crystals therefore consists primarily of solidified BaCN₂ flux and BaTaO₂N containing a large amount of BaO in the form of stacking defects, similar to the results obtained in work with the SrTaO₂N-Sr₂TaO₃N system.⁵⁰

Ba₂TaO₃N was generated as a thin surface layer around the BaTaO₂N perovskite crystals recrystallized from the BaCN₂ melt. In the melt, layers of Ba-rich phases such as BaO were randomly inserted between the BaTaO₂N perovskite layers around the edges of the perovskite crystals. These phenomena explain why the crystallinity of the as-grown BaTaO₂N was slightly low and why a trace amount of a Ba₂TaO₃N impurity is evident in the powder XRD pattern in **Figure 1(a)**. These data suggest that the starting BaTaO₂N powder was dissolved to the molten BaCN₂ followed by the recrystallization of BaTaO₂N single crystals with a uniformed perovskite-type atomic orientation and the precipitation of solid phases including Rudelesden-

Figure 2. (a) TEM bright-field image of a thin sample specimen, (b) the SAED image of the area encircled in (a), and (c) a high magnification HAADF-STEM image of the encircled area. In (c), green, yellow, and red spheres indicate Ba, Ta, and O/N anions, respectively. The structural model was drawn using the VESTA software package.⁴⁹

Popper type Ba₂TaO₃N which partially contain an insertion of BaO layers. The formation mechanism of Ba-rich oxynitrides such as Ba₂TaO₃N, which contains excess BaO layers between BaTaO₂N can be surmised in several routes. (1) they were formed as metastable phases at the beginning of the recrystallization from the flux. These phases were generated at the interfaces between the solid BaTaO₂N and the molten BaCN₂ during the growth of BaTaO₂N crystals at high temperatures. That is, crystals of BaTaO₂N did not directly recrystallize from the solution of this compound in the BaCN₂ flux. (2) BaTaO₂N simply recrystallizes from the

BaCN₂ solvent and then Ba-rich phases are formed by a decomposition of BaCN₂ during the heating.

Growth of the BaTaO₂N perovskite crystals

Some grain growth was observed in the reddish products for most of the preparation conditions in the presence of BaCN₂, as summarized in **Table 1**. The primary particles in the as-prepared BaTaO₂N powder after ammonolysis had rounded morphologies and were 40 to 150 nm in size. These particles formed irregular aggregates approximately 2 to 3 μm in size, as depicted in **Figure 4(a)**. The shape and size of the aggregates also changed with increases in the amount of BaCN₂ in the flux during heating at 910 °C for 30 min. A slight crystal growth occurred in the case of the precipitation of BaTaO₂N from the 17 mol% BaCN₂ flux (**Figure 4(b)**), while cubic crystals reflecting the euhedral form of the perovskite-type structure that appeared at 22 mol% are shown in **Figure 4(c)**. These powder products prepared with small amount of BaCN₂ (≤ 22 mol%) are composed of tiny particles due to a lack of flux enough to grow BaTaO₂N crystallites. Larger red crystals were observed when using 46 mol% BaCN₂ and the particle size increased to 3.1 μm at 46 mol% BaCN₂, as can be seen in **Figure 4(e)**. Micron-sized BaTaO₂N crystals were grown only in the cases which the exterior region of the original BaTaO₂N particles were dissolved to the BaCN₂ flux and interior of the BaTaO₂N particles are remained as the nucleus for the crystal growth. In the samples containing micron-sized BaTaO₂N crystals (**Fig. 4(d)** and **(e)**), large crystals several microns in size coexisting with many submicron particles were observed. Slow precipitation from a dilute BaTaO₂N solution in the BaCN₂ flux was expected to increase the crystal size. Rather, aggregates of small cubic crystals were present when using high BaCN₂ concentrations (≥ 67 mol%), as depicted in **Figure 4(f)**.

The original BaTaO₂N powder was completely dissolved in a large amount of molten BaCN₂ at high temperatures and tiny particles recrystallized by homogeneous nucleation.

In one trial, the cooling rate was increased from 1.8 to 300 °C/h using 46 mol% BaCN₂. Under these conditions, the crystal size was found to decrease to less than 0.5 µm, as shown in **Figure 4(g)**. This suggests that slow cooling is required to obtain larger BaTaO₂N crystals from a BaCN₂ flux. The effect of the hold duration at 910 °C was also investigated by changing the hold time from 30 min to 24 h using the 46 mol% BaCN₂. The maximum particle size from this trial was only 0.4 µm, as is evident in **Figure 4(h)**. The formation of much smaller crystals as compared to those obtained after 30 min (**Figure 4(e)**) is attributed to a partial loss of the molten BaCN₂ flux by evaporation and decomposition during the heating process.^{43,44} Heating the reaction system to the melting point of tetragonal BaCN₂ (910 °C)^{43,44} is necessary to dissolve BaTaO₂N powder, but the duration at 910 °C should be as short as possible because BaCN₂ flux is lost above 910 °C, which results in a condensation of the solution to form only tiny crystallites. Therefore, it is important to maintain a sufficient amount of the BaCN₂ melt during the crystal growth, even though this is difficult in practice.

Piezoelectric analyses of BaTaO₂N single crystals

Reddish BaTaO₂N crystals grown with 46 mol% BaCN₂, a 30 min hold at 910 °C and a cooling rate of 1.8 °C/h, which were several microns in size, were assessed by applying PFM because they were not large enough for an ordinary measurement of electrical property. After leaching with nitric acid, these crystals were found to consist of phase-pure BaTaO₂N perovskite (see **Figure S2** in the **Supporting Information**) with lattice parameter $a = 0.41118(3)$ nm, which is consistent with the literature value ($a = 0.41128$ nm).¹³ The crystals were cubic, reflecting the cubic lattice in the average structure, although local symmetry breaking in the *cis*-type configuration around TaO₄N₂ octahedra has been reported. Prior to studying piezoelectric properties, SHG assessments were performed for BaTaO₂N crystals obtained under the same conditions to confirm the presence of non-centrosymmetric structure for ferroelectricity. In these trials, a 1064 nm laser beam with a diameter of approximately 100 μm was irradiated to the surface of the BaTaO₂N crystal aggregate at 30 °C, to avoid the partial loss of nitrogen from the crystals as a result of laser heating. In response, a weak secondary harmonic wave at 532 nm was observed (**Figure 5(a)**), confirming the presence of non-centrosymmetric regions in the BaTaO₂N crystals. This result demonstrates that local symmetry was disturbed by the co-presence of oxygen and nitrogen atoms in the reported centrosymmetric *Pm-3m* crystal structure. This nonlinear optical effect is consistent with the occurrence of the ferroelectric piezoresponse discussed below.

Figure 5. SHG spectra acquired from **(a)** BaTaO₂N crystal aggregates and **(b)** reference amorphous silicon dioxide powder at room temperature.

Electrical short was avoided by forming island structure, which is fabricated by the FIB grooving of connected Pt deposited side-wall to bottom Au electrode and copper substrate (see **Figure S1**). A square region with dimensions of $2.5 \times 2.0 \mu\text{m}^2$ was found out in the AFM topographical image of a BaTaO₂N single crystal and covered with a Pt top electrode, as shown in **Figure 6(a)**. An AC electrical voltage of 2Vp-p (peak to peak voltage) was subsequently applied to the present crystal at various temperatures. It was found that a much higher electrical voltage could be applied to the present highly-insulating crystals than the previous ceramic samples, which showed serious current leakage at voltages as low as 10 V.^{25,26} Hysteresis loops were observed in the piezoresponse over the temperature range of 30 to 90 °C under electrical voltage of less than 40 V, but there was no polarization switching over the voltage range applied. PFM phase hysteresis loop and PFM amplitude butterfly curve originated from ferroelectricity

were clearly observed at 120 °C in an applied electrical voltage of ± 100 V as shown in **Figure 6(b)** and **6(c)**. The maximum applied electric field was roughly estimated as 460 kV/cm. The coercive voltage was 50 to 60 V according to the phase and amplitude signals, although a higher voltage was required to induce clear piezoresponse phase switching.

Note that electrostrictive effect was observed in amplitude curve due to an application of very high voltage. Here, polarization(P)-electric field(E) hysteresis loop should be measured, however it is very difficult to execute due to following reasons; (1) enough charge could not be obtained using island system because of very small top electrode size, and (2) artificial charge from air capacitor between cantilever and top electrode might be included in measurement. Reliable capacitance value could not be obtained due to the same reason with (1). Therefore, although we could not measure exact P - E hysteresis loop, clear polarization switching was obtained in this SS-PFM measurement, indicating that BaTaO₂N crystal is truly ferroelectric material.

The observed ferroelectric polar phase alternation is consistent with the presence of PNRs in the BaTaO₂N, which has previously been suggested by many researchers as indicating the favorability of *cis*-type anisotropic anion configurations and the formation of spontaneous polarization in oxynitride perovskites (**Figure 7(a)**).^{17,18,21} Previous neutron diffraction analyses have found that the average crystal structure of

Figure 6. (a) AFM topographical image of a BaTaO₂N crystal (indicated by the dotted red square), (b) piezoresponse amplitude curve obtained at 120 °C, and (c) its ferroelectric phase signal graph.

BaTaO₂N is that of a cubic perovskite with space group $Pm-3m$ and $a = 0.41128 \text{ nm}^{13}$, in which nitrogen atoms are randomly present, together with oxygen atoms, at $3c$ sites. However, this compound has also been assumed to contain TaO₄N₂ octahedra having *cis*-type coordination, similar to tetragonal SrTaO₂N.²¹ The nitrogen atoms form the *cis*-type configurations to consist the helical Ta-N chain motifs in the apical linkages to TaO₄N₂ octahedra. The PNRs in **Figure 7(a)** are formed by the interaction between two kinds of helical Ta-N chain coil motifs; clockwise and anti-clockwise. These are present in the domain structures of PNRs even at room temperature, which is below the Burn's temperature for this compound (**Figure 7(b)**).⁵¹ The concentration of these PNRs is low, as suggested by the weak intensity of the SHG signal shown in **Figure 5(a)**, because the domains are almost averaged in the total crystal structure. The polar domain size gradually grows with increases in the applied electrical field bias, as summarized schematically in **Figure 7(c)** and **7(d)**.

In a preliminary experiment, polarization phase alternation was observed at high temperature (e. g. 100 °C), while no phase switching was detected in the same voltage range at 30 °C. This suggests that polarization phase in PNRs could be more easily altered by the assist of heat as in the case of typical relaxor ferroelectrics like Pb(Mg_{1/3}Nb_{2/3})O₃.⁵² The polarization was saturated above $\pm 60 \text{ V}$ in the applied electric field to show the clear ferroelectric piezoresponse at approximately 100 °C. The present crystals were sufficiently insulating so as to allow the application of electrical fields as high as $\pm 100 \text{ V}$, which is by far higher than the maximum values previously reported for ceramic samples (up to approximately $\pm 10 \text{ V}$).^{25,26} This characteristic enabled saturation of the polarization of BaTaO₂N crystals to produce

Figure 7. (a) Two sets of polar nano regions in the crystal structure of BaTaO₂N with *cis*-type anion ordering as simulated by molecular dynamics calculations. Brown, green, blue, and purple spheres indicate Ba, Ta, O, and N, respectively. A part of (a) is reproduced from ref. 21 with the permission of the American Chemical Society. Structural models were drawn using the VESTA software package⁴⁹, (b) polar nano regions present in the average $Pm\bar{3}m$ cubic crystal lattice in which most of the oxygen and nitrogen atoms are randomly distributed at $3c$ sites, (c) polar nano regions growing along the applied electric field, and (d) the polarization saturated at applied electric fields higher than ± 60 V.

clear butterfly-like PFM signals. Investigations of the structures of BaTaO₂N single crystals after the polarization process are now under investigation.

Conclusions

Small cubic crystals of perovskite-type BaTaO₂N were grown to a size of approximately 3.1 μm in molten BaCN₂. The crystal growth is considered to proceed through the formation of Ba-rich Ba₂TaO₃N. Maintaining the BaCN₂ melt for a prolonged time span was an effective means of promoting crystal growth. These small BaTaO₂N crystals showed a clear ferroelectric piezoresponse, indicating the presence of polarization that could be switched by applying an external electrical field at 120 °C in PFM measurement. This polarization switching of self-standing oxynitride perovskite without electrical leakage was observed for the first time. This finding clearly confirmed the ferroelectric properties of this material in conjunction with polar nano regions. The co-presence of nitrogen with oxygen in the centrosymmetric average crystal structure of oxynitride perovskites partially lowered the local crystal symmetry to produce polar nano regions with a non-centrosymmetric structure. These results should assist in identifying a number of new ferroelectric materials based on mixed anion compounds especially oxynitrides.

Author Contributions

This research was mainly conducted by A.H., Y.M. and S.K. All of authors contributed to paper preparation. The growth of BaTaO₂N crystals and XRD analyses were conducted by A.H. SHG measurements were performed under supervision of M.T. Elemental analyses of BaTaO₂N crystals and mono-layered capacitor fabrication was performed with the by technical assistance of T.E. PFM measurements were performed by A.H., S.Y., and M.I.

Funding Sources

This research was supported in part by a KAKENHI Grant-in-Aid for Scientific Research (A) (no. 24245039), a Research Fellowship (no. 19J10301), and a grant for Scientific Research on Innovative Areas “Mixed Anion” (no. JP16H06439) from the Japan Society for the Promotion of Science (JSPS), and as a part of the “Nanotechnology Platform” Program of the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan (grant no. A-18-HK-00100), and Collaborative Research Project of Laboratory for Materials and Structures, Tokyo Institute of Technology.

ACKNOWLEDGMENT

SHG measurements were technically supported by Hiroki Mizuno and Kazuki Shimizu (Division of Physics, Faculty of Science, Hokkaido University). The TEM observations were conducted with the assistance of Ryo Ohta (Hokkaido University Faculty of Engineering Technical Center, Japan).

SYNOPSIS

Reddish cubic crystallites of perovskite-type BaTaO₂N were grown up to 3.1 μm in size using BaCN₂ as a flux. Ferroelectric piezoresponse with a clear polarization phase switching was observed on the oxynitride crystals for the first time in PFM. The ferroelectricity is consistent with the previously suggested local symmetry breaking due to the anisotropic anion ordering in centrosymmetric average structure.
