ABSTRACT

Developing a technology to terminate chalcogen vacancies for transition metal dichalcogenides is a crucial task for applications, such as diodes, transistors, and sensors, because chalcogen vacancies degrade the electronic and optical properties. This article reports a healing method of S vacancies in MoS₂ by high-pressure annealing under 5 atm of S vapor pressure. The crystal quality after a mechanical transfer, S annealing, and vacuum annealing was systematically studied by observing the photoluminescence (PL). The remarkable recovery of the A exciton emission peak in the PL spectrum indicated repair of the crystal quality in MoS₂ by the S annealing. We also demonstrated that the S vacancies could be terminated by Se atoms using a high-pressure annealing

method. The crystal quality of $\text{MoS}_{2(1-x)}\text{Se}_{2x}$ alloy was confirmed by transmission electron microscopy and electron diffraction.

KEYWORDS: high-pressure annealing, MoS_2 , S vacancies, photoluminescence, chemical vapor deposition, monolayer

After the scotch tape method was established to make graphene from graphite,¹ many other layered materials have attracted much attention in the past decade.²⁻⁷ Particularly, semiconducting transition metal dichalcogenides (TMDCs), such as MoS_2 ,^{8,9} MoSe_2 ,¹⁰ WS_2 ,¹¹⁻¹³ and HfS_2 ,¹⁴⁻¹⁶ have been widely studied due to the unique electronic and optical properties derived from the non-zero bandgap unlike graphene. The non-zero bandgap is a crucial feature for practical applications such as digital circuits and low-power-consumption electronics.

Although the scotch tape method is still used for the fundamental science of layered materials, chemical vapor deposition (CVD) is one of the best methods to make high-quality monolayer TMDCs on a wafer-scale. Due to the recent progress of CVD,¹⁷⁻¹⁹ the crystal quality of MoS_2 grown on sapphire is comparable to that of exfoliated MoS_2 . Since the crystal quality governs the electronic and optical properties, such as carrier mobility^{20,21} and the intensity of the photoluminescence (PL),^{20,22,23} it is vital to maintain the crystal quality during the device fabrication process, for example, microscopic peeling off from the original substrate, mechanical transfer to another substrate, and lithography for microfabrication. However, the chemical wet process during mechanical transfer may cause damage to the MoS_2 due to the relatively weak bond between the Mo and S. In other words, the formation of S vacancies and oxidation easily occur

during the mechanical transfer. Therefore, it is crucial to establish a defect healing technology for high-performance transistors,^{8,24} photovoltaics,²⁵ and phototransistors.²⁶ While the dipping in a thiol solution (thiol healing) was suggested as a simple defect healing method in 2012,^{24,27,28} several researchers insisted that thiol molecules were merely physisorbed on the MoS₂.²⁹ The inconsistent conclusions of the thiol healing are probably because the property of MoS₂ is sensitive to the small number of S vacancies (even less than 1%), and it is difficult to detect them in the monolayer MoS₂. Thermal annealing is another healing technology to improve the structural order and release the stress. However, the thermal annealing under argon, oxygen, and vacuum resulted in non-stoichiometric MoS₂ due to the volatility of the S atoms.³⁰⁻³² In order to resolve these issues, an alternative defect healing method should be established.

In this study, a high-pressure S annealing method was proposed as a defect healing method. A high-quality MoS₂ as the standard material was synthesized on sapphire by CVD because it is well-known that the monolayer MoS₂ grown on sapphire has the best quality due to its epitaxial growth.^{17,18} The MoS₂ grown on the sapphire was transferred to a SiO₂/Si substrate to investigate the influence on the quality of the monolayer MoS₂. The defective transferred monolayer MoS₂ was annealed under 5 atm of S vapor pressure to heal the S vacancies. Vacuum annealing was also carried out to examine the variation in the crystal quality. The change in crystal quality was systematically studied by observing the PL that is sensitive to the defects to determine how the mechanical transfer, high-pressure S annealing, vacuum annealing affects the crystal quality. Se annealing was conducted to investigate whether Se atoms cure the S vacancies, which can be used to make an MoS_{2(1-x)}Se₂ alloy by post annealing.

RESULTS AND DISCUSSION

Monolayer MoS₂ was grown on sapphire based on the gas-phase reaction of MoO₃ and S vapor using a specially designed separate-flow-system CVD. The detailed growth procedure is described in the METHODS section and supplementary information. Figures 1(a) show an optical microscopic (OM) image of the triangular monolayer MoS₂ with a single-crystal domain on sapphire. The two distinctive crystallographical orientations of the MoS₂ domains can be seen in the OM image and interpreted as the epitaxial growth due to the lattice match.⁷ The orientation histogram shown in Fig. 1(b) illustrates that most of the single triangle domains are oriented to 0° or ±60°, which is consistent with the previously reported epitaxial MoS₂ monolayer.³³ Since the in-plane lattice constant of sapphire (0.476 nm) is approximately 1.5 times greater than that of MoS₂ (0.315 nm), a 3 × 3 structure of the MoS₂ fits on a 2 × 2 structure of the sapphire as shown in Fig. S1.¹⁸ While the MoS₂ grown on the sapphire showed a nearly perfect triangle domain and high orientation, the distorted triangle and randomly oriented MoS₂ formed on the SiO₂/Si is shown in Fig. S2. The highly-oriented domains indicated that the quality of the MoS₂ monolayer on the sapphire was superior to that on the SiO₂/Si. The thickness uniformity of MoS₂ grown on sapphire was observed by the homogeneous color contrast of the triangle domains as seen in Fig. 1(a). Furthermore, the height of the MoS₂ domains was measured to be 0.65 nm by AFM as seen in Figs. 1(c) and (d), which agrees well with the previously reported thickness of the monolayer MoS₂.^{19,34,35}

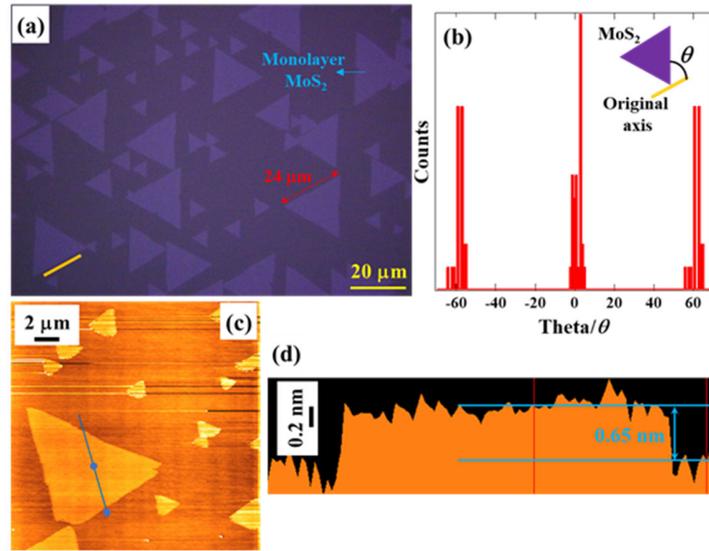

Figure 1. (a) Microscopic image of monolayer MoS₂ grown on sapphire. The orange bar is the original axis (0°) used to measure the orientation angles (theta) to make the histogram shown in (b). (b) An orientation histogram of MoS₂ monolayer to illustrate the epitaxy between MoS₂ and sapphire. The inset shows the geometrical relationship between the original axis and MoS₂ to measure theta. (c) An AFM image of monolayer MoS₂. (d) Line profile at the blue line in (c) to show the thickness of the MoS₂ monolayer (0.65 nm).

We further confirmed the quality of the triangle-domain single-crystal monolayer MoS₂ by obtaining Raman and photoluminescent (PL) spectra as shown in Figs. 2(a) and (b), respectively. The Raman and PL spectra of the MoS₂ monolayer grown on the SiO₂/Si substrate are also shown for comparison. Two characteristic peaks of E_{2g}¹ at 385.6 cm⁻¹ and A_{1g} 405.7 cm⁻¹ in the Raman spectra represent the in-plane vibrational mode and out-of-plane vibrational mode of MoS₂, respectively. The shoulder peak at 415.0 cm⁻¹ was ascribed to the sapphire. The frequency difference between the E_{2g}¹ and A_{1g} peaks (20.1 cm⁻¹) is close to the reported value of the

monolayer MoS₂.^{18,36} The crystal quality of the MoS₂ monolayer on the sapphire was better than that on the SiO₂/Si because the full width at half maximum (FWHM) of the A_{1g} peak for the MoS₂ grown on the sapphire (5.43cm⁻¹) was narrower than that on the SiO₂/Si (9.52cm⁻¹). The intensity of the Raman spectra in Fig. 2(a) was scaled to compare the FWHM. The PL spectrum (Fig. 2(b)) shows the strong A excitonic peak located at 655 nm (1.81 eV) while the negligible B excitonic peak (616 nm) was observed. The sharp peak located at 694 nm originated from the sapphire. The narrow FWHM (~25 nm) and intense A excitonic peak indicated the significant optical quality and few defects in the monolayer MoS₂ because the PL spectra, especially the intensity of the A excitonic peak, is sensitive to the crystal quality.^{21,23} The broader and less intense PL peak of MoS₂ grown on the SiO₂/Si were probably due to the defects of the S vacancies, the charge traps on the SiO₂ surface, and the distortion of the MoS₂ structure. The chemical compositions of the monolayer MoS₂ grown on the sapphire and SiO₂/Si were determined to be 1:2.02 and 1:1.79, respectively, by XPS (Fig. S3). The Mo/S ratios are consistent with the result of the OM image, Raman, and PL spectrum that show few S vacancies exist in the MoS₂ grown on the sapphire while there were some S vacancies in that grown on SiO₂/Si.

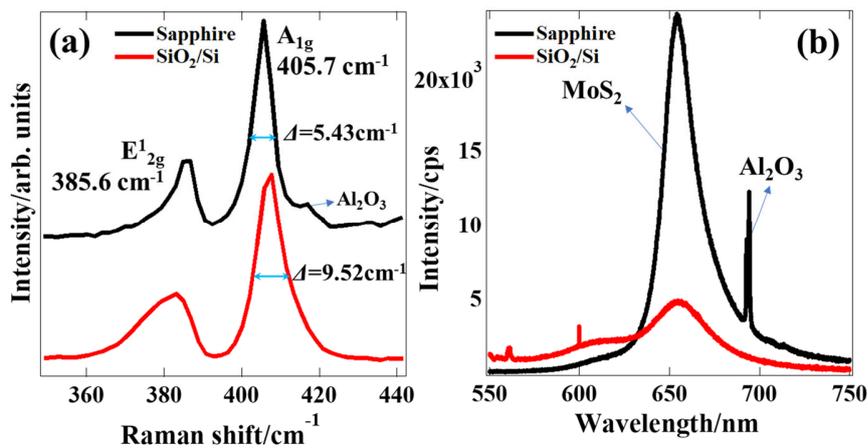

Figure 2. (a) Raman spectrum of monolayer MoS₂ grown on sapphire (black) and SiO₂/Si (red). Two distinctive vibrational modes of E_{12g}¹ and A_{1g} illustrate the formation of MoS₂. The crystal quality of MoS₂ grown on the sapphire was superior to that on SiO₂/Si because of the narrower FWHM. (b) PL spectrum of monolayer MoS₂ grown on the sapphire (black) and SiO₂/Si (red). The strong A exciton emission peak indicates the high crystal quality of MoS₂ on the sapphire.

MoS₂ grown on the sapphire was used as a standard sample to investigate how the mechanical transfer, S annealing, and vacuum annealing affect the quality of the monolayer MoS₂ because the defect formation and healing can be detected by observing the PL.³⁷ Each step of mechanical transfer, S annealing, and vacuum annealing was carried out as follows. First, the monolayer MoS₂ grown on the sapphire was transferred onto a SiO₂/Si substrate by the chemical wet process according to Ref. 38. Next, the transferred MoS₂ was annealed in a sealed quartz tube at 800 °C for 30 min under 5 atm of S vapor pressure that was estimated by the ideal gas equation ($pV=nRT$). Lastly, the sample was annealed under a vacuum of 10⁻³ Pa at 800 °C for 30 min. The detailed procedures of the mechanical transfer and S annealing are described in the METHODS section and supplementary information. Figure 3 shows the PL spectra of MoS₂ (i) grown on sapphire, (ii) transferred on SiO₂/Si, (iii) annealed in the S atmosphere, and (iv) annealed under vacuum. Broadening the peak and lowering the intensity of PL for the transferred MoS₂ illustrate that strain or/and defects were induced in the lattice because a pronounced peak located at 655 nm from the A exciton is easily quenched by strain and defects. The recovery of the peak sharpness implies that the strain or defects was healed by the S annealing. Vacuum annealing introduced many defects (S vacancies) again, resulting in lowering the intensity.

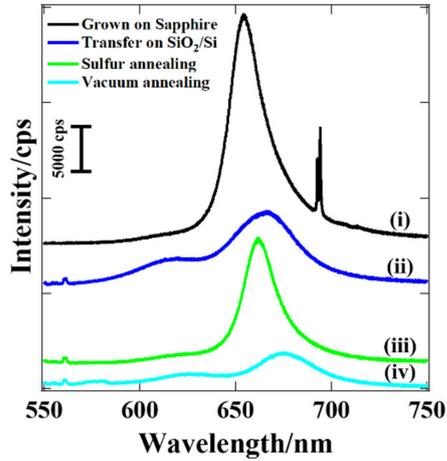

Figure 3. PL spectra of MoS₂ (i) grown on sapphire (ii) transferred on SiO₂/Si (iii) annealed under 5 atm of S vapor pressure (iv) annealed under vacuum. The peak intensity of the A exciton shows the crystal quality of MoS₂.

In order to quantitatively analyze the PL spectra, each spectrum was deconvoluted with three or four emission peaks (Gaussian-Lorentzian function) including the A exciton peak. Each emission peak was labeled by X_A , X_B , X^- , and X_{be} as shown in Figs. 4(a)-(d). All the spectra were scaled to compare the results of the deconvolution. The sapphire peak located at 695 nm in Fig. 4(a) was removed to obtain a good fitting curve. X_A is the neutral A excitons as already mentioned, which is associated with direct optical transitions from the valence band to the conduction band. The emission peak at 616 nm (X_B) is due to the spin split of the valence band at the K-valley. The other emission peak at 678 nm (X^-) is derived from a trion which is a bound state of one exciton and one electron, in other words, a negatively-charged exciton. The weakest peak at 698 nm (X_{be}) appeared after the mechanical transfer is assignable to the bound excitons (X_{be}) that are neutral excitons bound to defects such as S vacancies. The spectral contributions from the four kinds of excitons are understandable by the schematic band diagram shown in Fig. 4(e).^{37,39} Figure 4(f) shows the

variation of the individual spectral contribution obtained from the deconvoluted curves and total intensity of the PL spectra. It should be noted that the X_A is sensitive to the carrier density because the excessive carrier is bound to the excitons (formation of trion), resulting in a quenching of PL from X_A .^{39,40} Since the S vacancies emit two extra electrons, the X_A peak strongly depends on the number of S vacancies. Besides, X_{be} can be used to estimate the defect density (S vacancies)³⁷ while X_B and X^- were hardly used to discuss the MoS₂ quality. The PL spectra of the as-grown sample on the sapphire (Fig. 4(a)) has a significant contribution from the X_A exciton and no contribution from the X_{be} exciton due to the high crystal quality (defect-free). Mechanical transfer of the MoS₂ onto a SiO₂/Si induced the defects, such as S vacancies, because the X_A peak decreased and X_{be} peak appeared (Fig. 4(b)). The chemical wet process during mechanical transfer may cause damage such as oxidation, wrinkles, and formation of S vacancies. The broad peak also indicates the disorder of the MoS₂ crystal structure. High-pressure annealing in the S atmosphere (Fig. 4(c)) recovered the crystal quality since the contribution of X_A returned to nearly the original value and the spectrum can be fitted without the X_{be} peak. However, the incomplete recovery of the total intensity implies that the influence of charge traps on SiO₂ and charge transfer from SiO₂ could not be eliminated by S annealing. These effects can be removed by using hexagonal boron nitride as the substrate.⁹ Vacuum annealing (Fig. 4(d)) drastically induced the S vacancies due to the volatility of the S atoms. A decrease in the total intensity shows the increase in the nonradiative recombination rate due to the defect states.

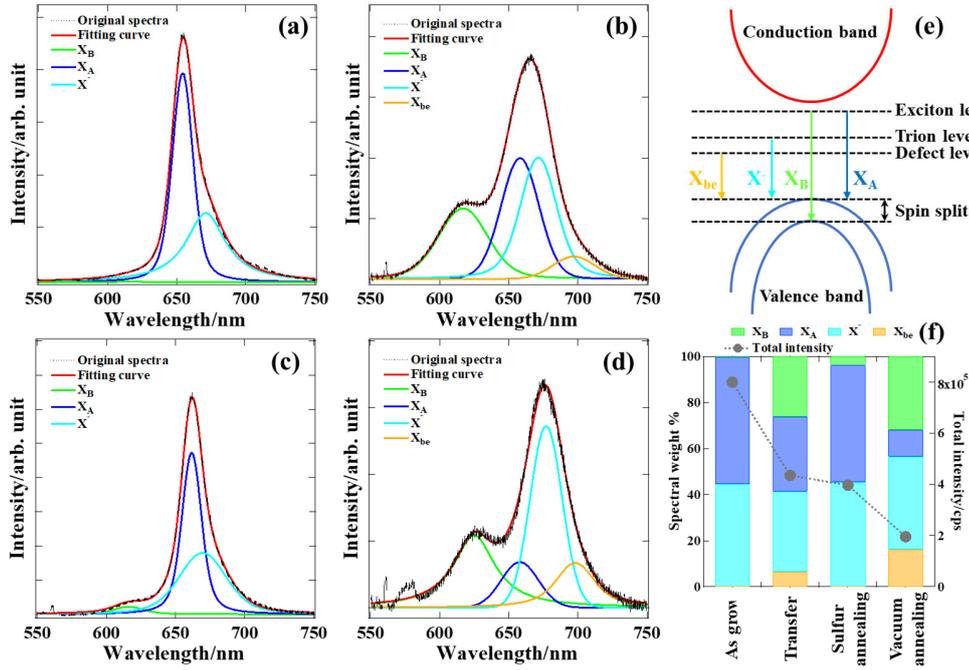

Figure 4. The deconvolution of PL spectra of MoS₂ (a) grown on sapphire (b) transferred on SiO₂/Si (c) annealed under 5 atm of S vapor pressure (d) annealed under vacuum. (e) Schematic band diagram of MoS₂ and four emissive transitions that were used to deconvolute the PL spectra. (f) The variation in the spectral weight and total intensity after each step.

If the S vacancies can be repaired by different chalcogenides, such as Se, it is useful to optimize the electric properties after the MoS₂ growth. Therefore, the MoS_{2(1-x)Se_{2x}} alloy was made by post-annealing under a Se atmosphere in a quartz tube (the same pressure and temperature as the S annealing) using the defective MoS₂ created by vacuum annealing. The formation of MoS_{2(1-x)Se_{2x}} was confirmed by its Raman and PL spectra as shown in Fig. 5. The Raman and PL spectra of the transferred and vacuum annealed samples are also shown for comparison. The Raman spectrum shows that the Se-Mo vibrational modes (A_{1g} and E_{2g}) located at 282 and 302 cm⁻¹ were observed after the Se annealing while only the S-Mo modes were seen before the Se annealing. There still remained two peaks of MoS₂ located at 380 cm⁻¹ (E_{2g}(S-Mo)) and 405 cm⁻¹ (A_{1g}(S-Mo)) even after

the Se annealing. The peak position of the $E_{2g}(\text{S-Mo})$ vibrational mode shifted to a lower frequency because the S-Mo bonding would be softened by the incorporation of the heavy Se atoms, which is consistent with the previous reports.^{41,42} It has already been reported that the $A_{1g}(\text{S-Mo})$ was not significantly affected by the introduction of Se.^{41,42} The Se annealing was also carried out for the as-grown sample (without vacuum annealing) as shown in Fig. S4. Although a small A_{1g} peak was observed due to the S/Se exchange reaction, the two-step annealing (vacuum annealing and Se annealing) was more efficient to incorporate Se atoms into the MoS_2 .

Figure 5(b) shows the PL spectra of the transferred sample, vacuum-annealed sample, and Se annealed sample. The emission peak from the exciton (X_A) was red-shifted because the bandgap would become narrower due to the alloying with Se. The Se molar fraction was estimated from the center of the emission peak to be approximately 10%⁴¹. Non-recovery of the PL intensity did not mean many S vacancies remained (poor crystal quality) because the introduction of Se atoms quenches the PL⁴¹.

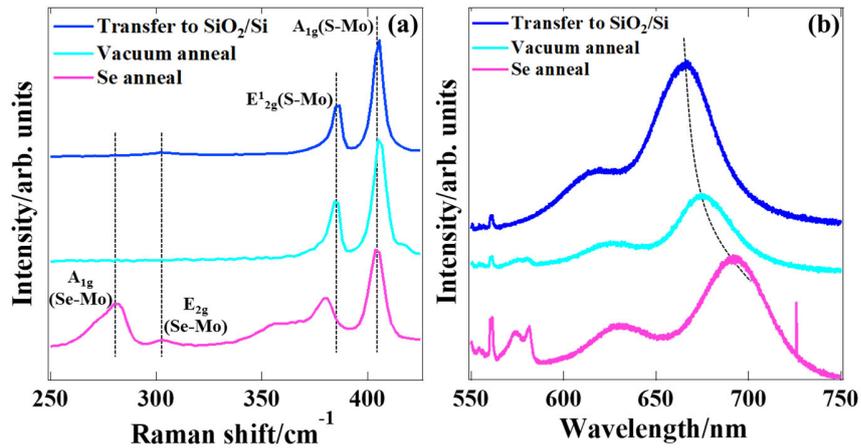

Figure 5. (a) Raman spectra of MoS_2 transferred to SiO_2/Si , annealed under vacuum, and annealed in Se atmosphere. Two peaks located at 282 and 302 cm^{-1} correspond to the Se-Mo

vibrational modes. (b) PL spectra of MoS₂ transferred to SiO₂/Si, annealed under vacuum, and annealed in Se atmosphere. The red shift of peak top shows the bandgap shrinkage due to the alloying with Se.

A TEM image and electron diffraction were acquired to confirm the crystal quality of MoS_{2(1-x)Se_{2x}} as shown in Figs. 6(a) and (b). The TEM-EDS indicates the inclusion of Se atoms after the Se annealing as shown in Fig. S5. The edge angle of the crystal (118°) reflects the hexagonal crystal system of MoS_{2(1-x)Se_{2x}}. Electron diffraction from the area marked with a blue circle in Fig. 6(a) revealed that the nanosheet of MoS_{2(1-x)Se_{2x}} was a single-crystal hexagonal structure. The *d* value calculated from a line profile (Fig. 6(c)) of the <100> direction (yellow line in Fig. (b)) was 0.271 nm which is good agreement with the previously reported (100) plane spacing of MoS_{2(1-x)Se_{2x}} with the same composition ratio (10% Se)⁴¹.

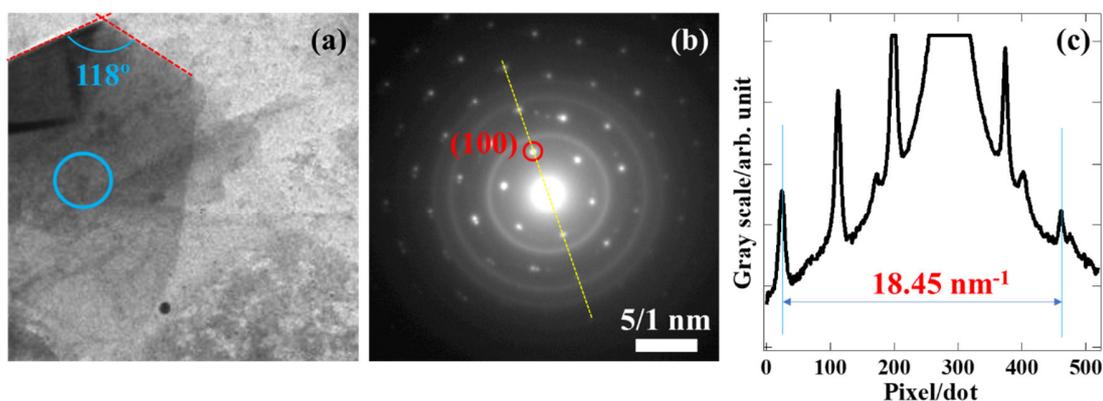

Figure 6. (a) TEM image of MoS_{2(1-x)Se_{2x}} after high-pressure annealing under Se atmosphere. (b) Electron diffraction of MoS_{2(1-x)Se_{2x}} obtained from the area marked with the blue circle in (a). (c) A line profile of the yellow line in (b) to calculate the *d* value of (100).

CONCLUSIONS

The influence of mechanical transfer, S annealing, vacuum annealing, and Se annealing on the monolayer MoS₂ was systematically studied by observing the PL spectra. Even though the mechanical transfer damaged the MoS₂, it can be repaired by high-pressure annealing under 5 atm of S vapor pressure. In addition, the S vacancies created by vacuum annealing were terminated with the Se atoms by high-pressure annealing. The post-annealing at elevated temperature can be used to heal the defects and modulate the composition ratio of the TMDCs, which could be an essential technique to fabricate practical electronic and optoelectronic devices.

METHODS

Growth procedure of monolayer MoS₂. The monolayer MoS₂ was synthesized by an atmospheric pressure CVD (APCVD) with a separate-flow system. The detailed geometry of our APCVD is shown in Fig. S6.^{7,43,44} In this system, we can separately control the temperatures of MoO₃, S, and substrate as well as flow rates of the MoO₃ and S lines to guarantee the controllability and reproducibility. MoO₃ (Kanto Chemical Co., Inc. >99.5%) and S (Kanto Chemical Co., Inc. >99.5%) powders were utilized as the source materials without further purification. 5 × 5 mm² sapphire (c-plane) and 1 × 1 cm² SiO₂(285 nm)/Si wafers were used as the substrates. The sapphire and SiO₂/Si were cleaned by the RCA (Radio Corporation of America) cleaning method⁴⁵ to remove any metal and organic contaminants. The sapphire was annealed in air for 1 hour at 1000 °C, which is a key to make the atomically smooth oriented MoS₂ monolayer.^{18,33} After the introduction of the substrate in a quartz tube, the system was purged with Ar. The temperatures of the MoO₃, S, and substrates increased to the set points while keeping the flow through the S line in order not have air enter the quartz tube. When the temperatures reached the set points, the Ar

flow through the MoO₃ line was set to 150 sccm to start the MoS₂ growth. The growth time was defined as the duration of Ar flowing through the MoO₃ line. After the growth of the MoS₂ monolayer, the furnace was naturally cooled while the S supply was maintained until the temperature of the substrate had decreased to 350 °C in order for the MoS₂ not to be oxidized. The reaction conditions of the temperatures, flow rates, and reaction time to make the monolayer MoS₂ are summarized at the bottom of Fig. S6.

Characterization of MoS₂/MoS_{2(1-x)}Se_{2x}. The morphology of the monolayer MoS₂ on the substrate was observed by an optical microscope (OM, OM mode of a laser microscope, VK-8710) and an atomic force microscope (AFM, SII SPI-3800). The quality of the monolayer MoS₂ was confirmed by Raman and PL spectroscopies (Reinshaw Invia) with 532 nm laser excitation. The chemical composition was measured by X-ray photoelectron spectroscopy (XPS, JPS-9200). The morphology and crystallinity of the MoS_{2(1-x)}Se_{2x} alloy were confirmed by transmission electron microscopy and electron diffraction (TEM, JEM-2010).

Mechanical transfer of the monolayer MoS₂ onto a SiO₂/Si substrate. A 1.0 wt% PMMA dichloromethane (DCM) solution was spin-coated on a monolayer MoS₂ grown on sapphire at a speed of 3000 rpm for 60 seconds. A polydimethylsiloxane (PDMS) film was placed on the sapphire substrate, then the substrate was cooled at 2 °C in a refrigerator. The surface of a SiO₂/Si was fluorinated under vacuum with a drop of trichloro(1H,1H,2H,2H-perfluorooctyl)silane for 12 hours. A mixture of PDMS and curative with a ratio of 10:1 was spin-coated at the speed of 1250 rpm for 30 sec, then the wafer was dried in an oven at 80 °C. The PDMS/PMMA/MoS₂ film was peeled off from the sapphire and transferred onto the fluorinated SiO₂/Si. Only the PDMS film could be removed by warming the SiO₂/Si wafer at 110 °C because the adhesion between the

PDMS and PMMA/MoS₂ weakened. The PMMA was washed away with DCM, then the SiO₂/Si was dried using a nitrogen gun.

Sulfur/selenium annealing. The MoS₂ (on substrate) was sealed in a quartz tube with S (Se) powder under a vacuum of 1.0×10^{-3} Pa. In order to avoid direct contact between the MoS₂ and S (Se), the substrate was located at the center of the quartz tube. The amount of S (Se) powder was calculated by the ideal gas equation to reach 5 atm of S (Se) vapor pressure. The quartz tube was annealed in a furnace at 800 °C for 30 min. The schematic illustration of the procedure is depicted in Fig. S7.

Vacuum annealing. The MoS₂ was sealed in a quartz tube under a vacuum of 1×10^{-3} Pa. The MoS₂ was placed in a furnace at 800 °C for 30 min. It should be noted that complete removal of air (oxygen) was critical to making adequate S vacancies because the oxidation or etching of MoS₂ occurred when it was higher than 5 Pa.
