Abstract: Renewable energy (RE) sources like wind and solar power have been introduced to power systems to make the energy market more sustainable and environmentally friendly. For this reason, the supply-demand mismatch in power systems is more severe than before, in terms of both frequency and magnitude. It is therefore necessary to reinforce the capability to make supply and demand adjustments in power grids. Here, we clarified the dynamic characteristics of biogas plants with combined heat and power (CHP) systems, that represent controllable RE power sources, and evaluated the possibility of using these systems as a new resource for supply-demand adjustments in the power grid. Additionally, the properties of the exhaust gas from the investigated CHP engines were measured as an environmental evaluation. We considered real-world biogas CHP systems operating in both Germany and Japan. Based on the results, biogas CHP systems have the potential to contribute to a long-term power equivalent adjustment such as tertiary control reserve (TCR) in Germany. However, these systems required several minutes between starting and stopping. Furthermore, increased emissions of methane and formaldehyde were measured when the CHP systems were starting up. We found that an operation with as few starts and stops as possible is therefore desirable.

Keywords:

Biogas, Combined heat and power (CHP), Load response, Power control, Emissions

## 1. Introduction

With the introduction of renewable energy (RE) power sources—whose output depends greatly on weather conditions—maintaining a real-time supply-demand balance becomes increasingly challenging. Due to such operational difficulties, ten electric power companies have been granted regional monopolies in Japan. In August 2011, the Special Measures Law

33 concerning the procurement of RE electricity by electric utilities was enacted, while on July  
34 1, 2012 a, "Feed-in Tariff Scheme for Renewable Energy" (FIT), requiring electric utilities  
35 to procure electricity generated using solar, wind, hydro, geothermal, and biomass for a fixed  
36 period at a fixed price set by the government, was introduced [1]. Power supply facilities  
37 were greatly affected by the Great East Japan Earthquake of March 11, 2011. Hence, there  
38 are growing expectations in Japan for a power source that can reduce greenhouse gas  
39 emissions while simultaneously ensuring energy security. The Japanese Ministry of  
40 Economy, Trade and Industry has also announced a policy to increase the ratio of RE power  
41 sources in the power supply mix by 2030 from about 22% to 24% [2]. Hence, the  
42 supply-demand mismatch is more severe than before in terms of both frequency and  
43 magnitude, and it is necessary to reinforce the supply-demand adjustment capability. Until  
44 now, supply-demand adjustments have been resolved by either increasing or decreasing the  
45 output of conventional power sources, such as thermal power plants, but the power  
46 generation capacity of such sources has decreased, and therefore the supply-demand  
47 adjustment capability of the power system has decreased. [3]. Additionally, conventional  
48 power plants, such as coal-fired plants, have an inferior dynamic performance and long cold  
49 start-up times of up to 48 hours [4]. In recent years the stabilization of power grids by  
50 controlling battery storages has been studied [5][6].

51 In many European countries the challenge of managing the fluctuations from renewable  
52 energy sources, such as wind power, has already been addressed. As far back as 2002 a study  
53 in Denmark investigated a self-supply strategy by managing the fluctuation from wind  
54 power with combined heat and power (CHP) units and selling excess electricity to  
55 neighboring countries [7]. In Germany and other parts of Europe, where FITs have been  
56 developed and RE power is increasing, CHP systems, such as biogas plants, are already  
57 being used to regulate capacity in transmission lines. In Germany, additional adjustment  
58 capacity is procured by the grid operator through auctions a day or week in advance. The  
59 power to be procured consists of three levels: primary control reserve (PCR), secondary  
60 control reserve (SCR) and tertiary control reserve (TCR) that are required to supply  
61 electricity within 30 s, 5 min and 15 min, respectively. German biogas CHP systems can  
62 participate in this market, typically as SRC or TCR, with operators of the power control pool  
63 managing individual plants and dealing with grid operators. Since the biogas plant would be  
64 remotely controlled by the pool operator, it is necessary to respond quickly to increasing  
65 power demand, and to shut down the CHP system when grid power becomes excessive [8].  
66 When a CHP system responds to a supply-demand target as an adjustment capability,  
67 responsiveness (speed) and adjustment capability (control range) are important parameters.  
68 Many studies have been published regarding the optimization of operational strategies, for

69 example for the day-ahead spot market [9], by increasing the power [10] and storage  
70 capacity of biogas plants [10, 11], by integrating heat pumps with CHP units [12] or by  
71 utilizing local resources ahead of central power plants [13,] or the profitability, by using  
72 thermal storage and Organic Rankine Cycle (ORC) technology [14], by simulating the  
73 effects of providing positive secondary control energy with biogas plants [15], by comparing  
74 operation of plants using solid, liquid and gaseous biofuels and the legislative and market  
75 conditions in Germany [16], by simulating different operational scenarios of a biogas plant  
76 participating in the spot market and control energy reserves [17] or by conducting an  
77 economical and ecological assessment based on different biogas plant configurations [18], of  
78 CHP systems. In a previous study a demand response program for an industrial customer  
79 was implemented using stochastic programming to solve short-term self-scheduling  
80 problems for CHP systems and enable them to participate in the power market more  
81 successfully [19]. In a different study the same authors investigated different demand  
82 response programs to serve the power and heat demands of the customer with minimum cost  
83 [20].

84 Another study has clarified that a CHP system can follow various load fluctuations in a  
85 microgrid [21]. Aghaei et.al. [22] investigated optimal operation strategies for CHP based  
86 microgrids regarding minimizing operational costs. The study shows that by implementing  
87 an optimized demand response program the operational costs could be reduced considerably  
88 [22]. A further study showed the necessity of precise assessment of reserve capacity of CHP  
89 units when managing load fluctuations in the power grid, when operating such units in  
90 conjunction with district heating networks [23]. These studies show that extensive work has  
91 been done regarding optimizing operational strategies of various CHP systems. However, all  
92 these evaluations have used simulations; there are few characteristic evaluations based on  
93 measurements using actual CHP systems. Furthermore, they do not address the specific  
94 demands of rural biogas CHP systems. Regarding actual on-site measurements Tappen et.al.  
95 [24] investigated the efficiency of 8 biogas CHP system over a long period of time (40,000  
96 to 60,000 operating hours). They have confirmed that the continuous operation of biogas  
97 CHP systems under a partial load is accompanied by a significant decline in electrical  
98 efficiency [24].

99 In this study, we clarified the dynamic characteristics of biogas CHP systems that represent  
100 controllable power sources among RE systems and evaluated the possibility of load response  
101 to utilize biogas CHP systems as a new supply-demand adjustment resource to supplement  
102 the output of naturally fluctuating power sources in rural Japan, where the management of  
103 load fluctuations in the power grid is very difficult [25].

104 The emphasis of the on-site measurements was on the load response of the biogas CHP

105 systems. Additionally, we measured the exhaust gas emissions during transient operation to  
106 evaluate the environmental impact of part load and load response operation. In previous  
107 studies both the greenhouse gas emissions, such as carbon dioxide (CO<sub>2</sub>) and methane  
108 (CH<sub>4</sub>), [26, 27, 28, 29] and the pollutant emissions, such as nitrous oxides (NO<sub>x</sub>) or carbon  
109 monoxide (CO) [26, 29, 30] have been investigated with on-site measurements at nominal  
110 load. When regarding GHG emissions the CHP exhaust emissions were identified as the  
111 second major source of methane emissions at biogas plants, after open storage of digestate  
112 [26, 28]. Considering the pollutant emissions under current Japanese law, biogas CHP  
113 systems do not fall under the category of fuel stipulated in the Air Pollution Control Law, so  
114 emissions are unregulated. However, in Europe such emissions regulations exist [31] and  
115 particularly in Germany the current standards for CHP systems with an electric rated output  
116 of over 1 MW were enforced recently [32]. A study showed, that when investigating 10  
117 biogas CHP systems in Italy, the investigated biogas plants were within prescribed limits, as  
118 well as the German limits, for NO<sub>x</sub> and CO over one year of monitoring, while transient  
119 operation was not specifically analyzed [27]. However, there are still very few studies  
120 regarding the environmental impact of part load and transient operation of biogas CHP  
121 systems. Hijazi et.al [33] investigated the specific greenhouse gas (GHG) emissions of  
122 biogas CHP units in flexible operation. They found that the specific GHG emissions under  
123 part load are higher than at full load due to the decrease in efficiency of the CHP unit at part  
124 load [33].

125 This study is necessary to utilize various resources in future power systems, with the  
126 viewpoint of increasing naturally fluctuating power sources, while maintaining stable  
127 operation of the power grid in rural areas of Japan. Additionally, the environmental impact  
128 of the management of fluctuations in the power grid is of the utmost importance when  
129 regarding the future operation of biogas CHP systems. This paper intends to bridge the gap  
130 between the proven technologies and practices in Germany and the current state in rural  
131 Japan, while considering the importance of environmentally friendly solutions and  
132 sustainable operation. Being a global issue, it is imperative to secure appropriate adjustment  
133 capacity efficiently and effectively by expanding the introduction of natural power sources,  
134 while utilizing currently available infrastructure, such as biogas plants.

135

## 136 2. Methodology

137 Nine biogas CHP systems from Japan and Germany generating electricity using biogas  
138 produced by fermentation were targeted. The raw material for the biogas was a mixture of  
139 corn feed and pig/dairy cow manure in Germany and dairy cow manure in Japan. Since the  
140 CHP systems were practical ones operating on farms in both countries, the properties of

141 biogas used in each CHP system were not uniform. The methane concentration of the  
 142 biogas on the German biogas plants ranged between 55% and 65%. All German biogas  
 143 plants implemented desulfurization of the biogas. At most small traces of H<sub>2</sub>S were detected  
 144 in the biogas. Additionally, two natural gas CHP systems were included for comparison to  
 145 the biogas CHP systems. These units were operated with so-called H-Gas (high-calorific  
 146 gas), which had a methane concentration of over 94% at the time of the measurements.  
 147 Table 1 gives an overview of the investigated CHP systems.

157

158

The load responsiveness depending on the output, as well as the startup and shutdown characteristics were investigated for all CHP systems. Fig.1 shows the measurement setup.

159

160

An electric power logger was installed after the generator of each CHP system. Using a PW3360<sup>1</sup> clamp-on power logger, voltage (V), current (A), and active power (kW) were measured at intervals of 1 s.

161

162

163

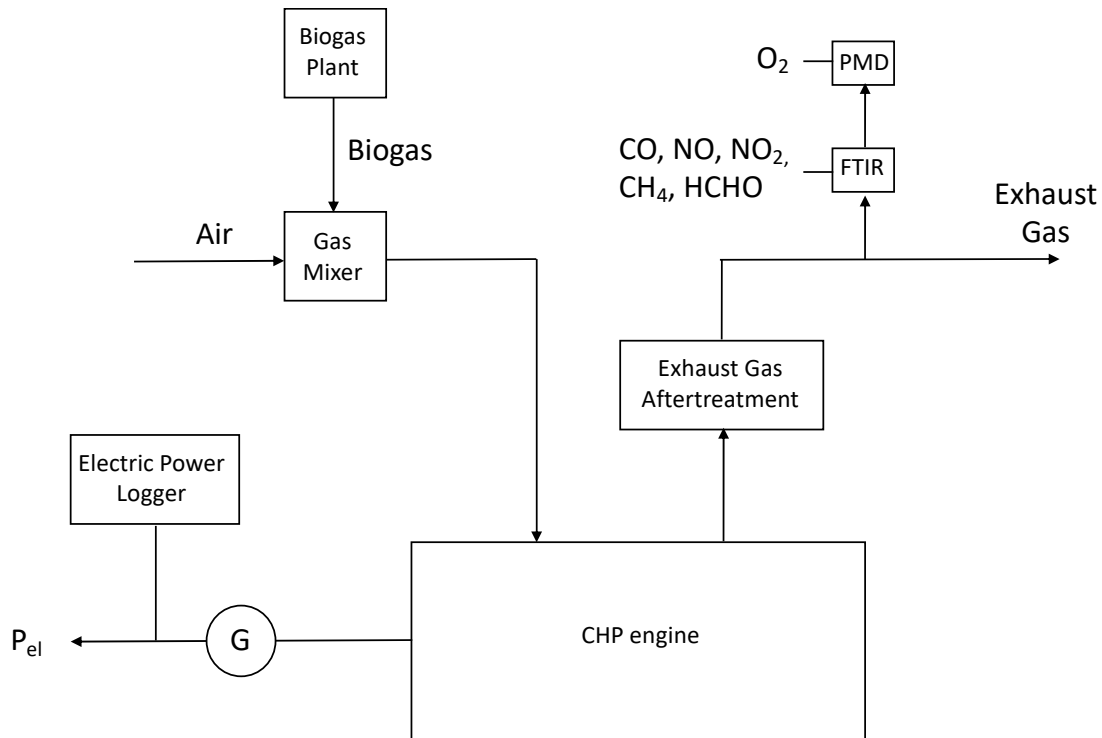

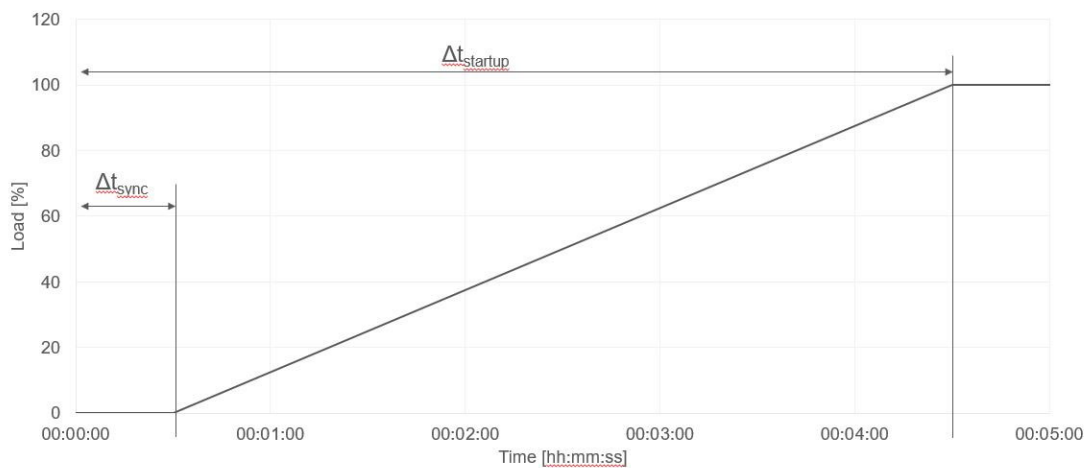

Fig.1 Measurement Setup

164

165

166

167 The startup response time  $\Delta t_{\text{startup}}$  was defined as the interval between the start command  
 168 (0 s) and when the CHP system reached nominal load (100%). This interval can be split into  
 169 two phases: the synchronization phase and the load ramp (Fig.2).

170

171

172

Fig.2 Startup response time

173 The step response time  $\Delta t_{\text{step}}$  was measured as the interval between giving the step command  
 174 and the CHP system reaching the specific load (Fig.3). The command value was changed in

175 10% steps starting from nominal load and ending at 50% of nominal load, before increasing  
 176 the power output stepwise back up to nominal load. Based on the step response time  $\Delta t_{\text{step}}$   
 177 and the value of the load step  $\Delta \text{load}_{\text{step}}$ , the step response speed or ramp  $m_P$  could be  
 178 calculated [34].

179

$$180 \quad \Delta \text{load}_{\text{step}} = (P_1 - P_2) * P_{\text{nominal}} \quad (1)$$

$$181 \quad m_P = \frac{\Delta \text{load}_{\text{step}}}{\Delta t_{\text{step}}} \quad (2)$$

182

Fig.3 Step response time

183

184

185 The environmental impact of the five German biogas CHP systems and two natural gas  
 186 CHP systems were also analyzed. The concentration of components from the exhaust gas of  
 187 the CHP systems were measured using a Fourier Transform Infrared (FTIR) CX40002  
 188 spectrometer. Gas was sampled continuously from the exhaust pipe of the CHP systems  
 189 downstream from the exhaust gas aftertreatment with a heated probe (Fig. 1). The exhaust  
 190 gas was supplied to the measuring device using a heated flexible tube that was constantly  
 191 heated to 180 ° C to prevent water precipitation in the device. Residual oxygen in the  
 192 exhaust gas was measured using a PMA10<sup>3</sup> paramagnetic oxygen analyzer and was measured  
 193 dry, i.e., when cooled to 5 ° C and water vapor is precipitated and removed from the sample.  
 194 During the step response and startup/shutdown experiments, concentrations of CO, NO<sub>x</sub>,  
 195 CH<sub>4</sub>, formaldehyde and sulfur dioxide (SO<sub>2</sub>) in the exhaust-gas were measured. These  
 196 values represent dry exhaust-gas by subtracting measured amounts of water vapor from  
 197 exhaust-gas. For the step response tests the concentrations of exhaust-gas components were  
 198 analyzed as mass concentrations (mg/m<sup>3</sup>) and referred to a residual oxygen concentration of  
 199 5 Vol.-% as specified by the German Emissions Standard TA Luft [35]. During the startup

200 and shutdown tests the direct volumetric exhaust-gas concentrations were analyzed. These  
 201 results were not referenced to 5 Vol.-% residual oxygen to prevent a distortion of the  
 202 measurements due to the varying residual oxygen content during the startup and shutdown  
 203 phases. All measurements were performed downstream from the exhaust gas catalyst. The  
 204 catalysts were in variable state of conditions due to the investigated biogas plants being  
 205 real-world plants in actual operation. No in-depth inspections of the catalysts or  
 206 measurements were made during the measurement campaign.

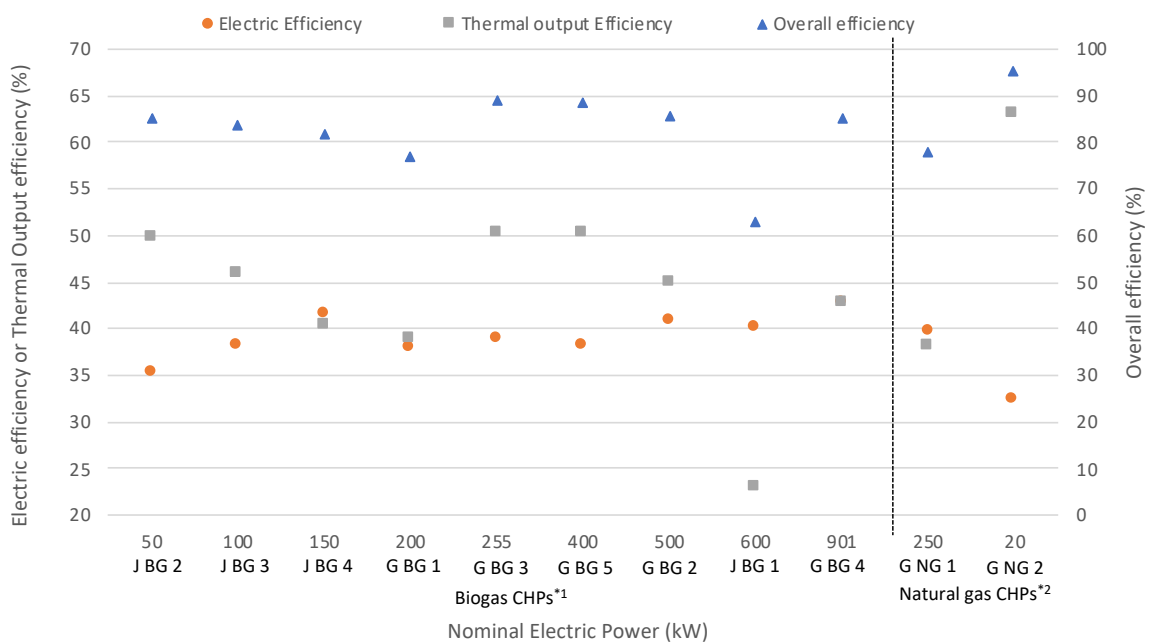

207

### 208 3. Results and discussion

#### 209 3.1 Biogas CHP system performance

##### 210 3.1.1 Electric and thermal outputs efficiency

211 Fig. 4 shows the values of electric efficiency and thermal output efficiency of each CHP  
 212 system at nominal load as published in the manufacturers data sheets.

213

214 Fig.4 Electric, Thermal output and overall Efficiency of the CHP systems

215 \*1 Biogas CHPs: Biogas combined heat and power

216 \*2 Natural gas CHPs: Natural gas combined heat and power

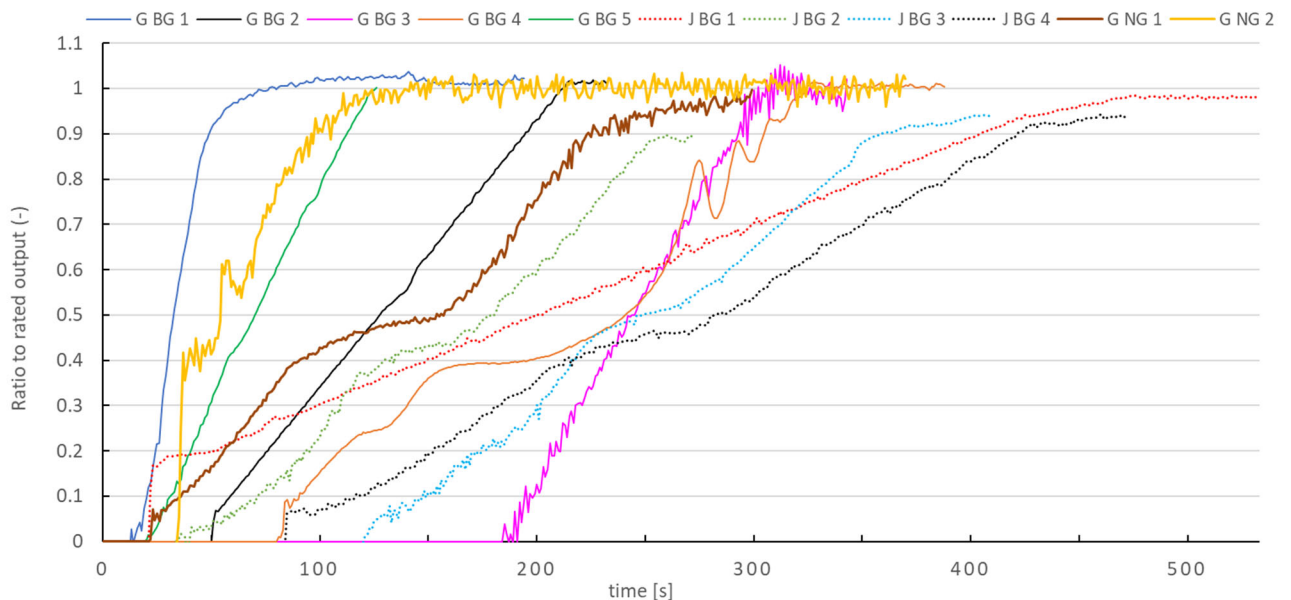

217

218 CHP systems, with a high electrical output, were more efficient than smaller CHP systems,  
 219 with the exception of “J-BG-4”, a state-of-the-art biogas CHP system with a high electrical  
 220 output efficiency. “J-BG-1” had an extremely low thermal output efficiency at 23.0%, due to  
 221 the manufacturer designing this unit considering the low heat utilization potential on site.

222 While “G-BG-3” and “G-BG-5” both reached high thermal output efficiencies of 50.2%. In  
 223 general, the thermal output efficiency is not only dependent on the technology used for the  
 224 CHP system, but also on the intended application of the heat. The thermal output efficiency  
 225 depends on the heat utilization. The average overall efficiency (electrical output + thermal  
 226 output) of German and Japanese CHP systems was 84.9% and 78.4%, respectively.  
 227 “G-NG-1,” a natural gas operated unit, uses a turbocharged lean burning engine. The  
 228 second baseline system, “G-NG-2,” is a naturally aspirated and stoichiometrically operated.  
 229

### 230 3.1.2 Startup dynamic characteristics

231 Fig. 5 shows the load characteristics during the startup process of the CHP systems.

232

233

Fig.5 Start-up response

234 \*1 BG: Biogas CHP

235 \*2 NG: Natural gas CHP

236

237 This represents the time that elapsed from the start command given to each device until it  
 238 reached the rated output. “G-BG-1,” “G-BG-5,” and “G-BG-2” took 72 s, 124 s and 211 s,  
 239 respectively, until the rated output was reached. This positively affected the stability of the  
 240 power output. Although it would be possible for these systems to contribute to TCR and  
 241 SCR, a PCR supply from a central power plant or storage battery would still be required.  
 242 “G-BG-4” and “G-BG-3” showed slower response times during the startup process than the  
 243 other German systems reaching rated loads in 324 s and 310 s, respectively. Moreover, they  
 244 show increased power output fluctuations in two separate situations: During the startup

245 process for both CHP systems; and, before the engine of “G-BG-3” could reach stable rated  
 246 operation.

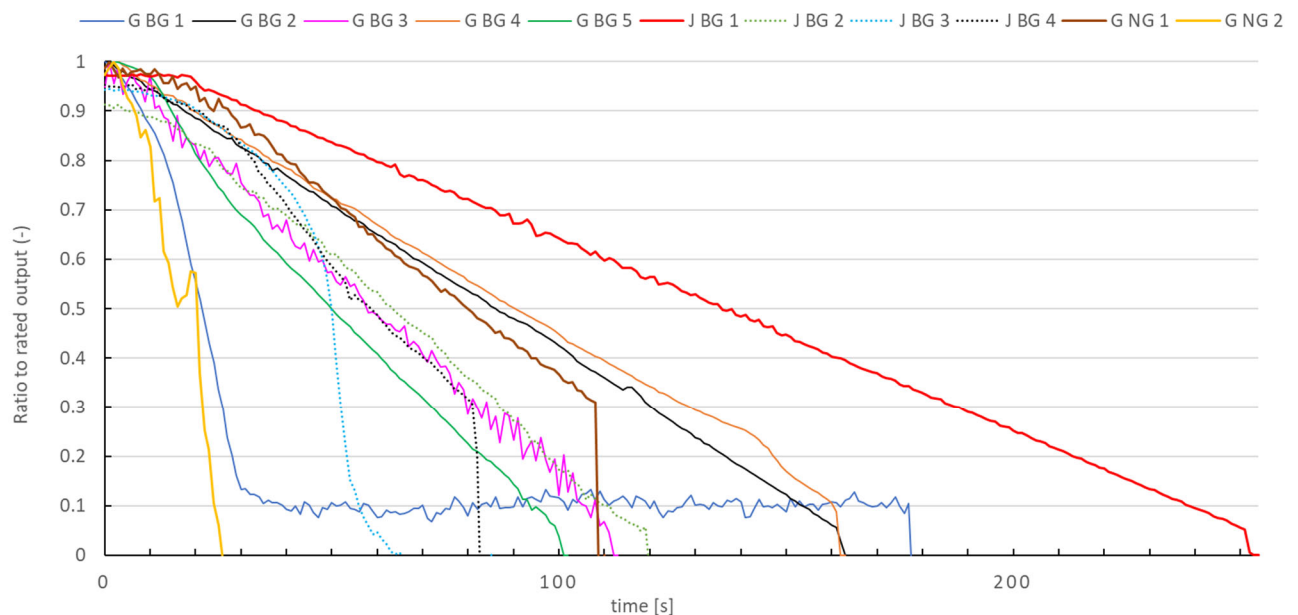

247 All Japanese biogas CHP systems took more than 400 s to reach the rated output from the  
 248 start command. “J-BG-2” has a better startup responsiveness than “J-BG-4” and they  
 249 reached their rated loads in 247 s and 456 s, respectively. It was observed that regardless of  
 250 the size of a CHP system, the output initially increased to about 40–50% of the rated output  
 251 after startup, and then, after a short stable operation at this load, continued increasing until  
 252 it reached the respective rated output.

253 “G-NG-2,” being a relatively small engine, reached the rated output at a faster rate, i.e.,  
 254 within 116 s, compared to “G-NG-1” (299 s). “G-NG-1,” which was issued with settings to  
 255 provide a SCR on the German power control market, reached the rated output in under the  
 256 required 5 min limit, but as slowly as possible to provide the most stable startup process  
 257 possible.

258

### 259 3.1.3 Shutdown dynamic characteristic

260 Fig. 6 shows the load characteristics when the CHP systems are shutdown.

261

262

Fig.6 Shut-down response

263 \*1 BG: Biogas CHP

264 \*2 NG: Natural gas CHP

265 This indicates the elapsed time from the issuance of a stop command during rated operation  
 266 until the output reaches 0 kW. After the generator connection to the grid is cut, the engines  
 267 of the CHP systems have a 30 s to 60 s cool down phase in idle operation that was not

268 included in the evaluation. Three general response characteristics could be defined from the  
269 experimental test once the stop command is issued: (1) The output of the stop characteristic  
270 decreases linearly. (2) The output decreases linearly to about 30–70% of rated output, then  
271 after a short period that load decreases to 0 kW at a faster rate. (3) The output decreases  
272 linearly to about 10% of rated output and after a certain time is reached at this load, the  
273 CHP shuts down.

274 For “G-BG-5”, “G-BG-4”, “G-BG-2” and “J-BG-2”, the behavior classified in (1) is  
275 observed. The output decreases at a constant rate for these systems. This is not suitable for  
276 applications requiring high load responsiveness. The time required for the power output of  
277 these systems to reach 0 kW was 101 s, 162 s, 163 s and 120 s, respectively. The result of  
278 “J-BG-1” is a stop characteristic based on an automatic shutdown which occurs when the  
279 level of the gasbag of the biogas plant reaches a certain value. This CHP system does not  
280 include a manual stop mechanism, so only startup and automatic shutdown responses could  
281 be assessed. “G-BG-3” and “J-BG-4”, show a behavior classified in (2). They adopt a control  
282 program that does not generate a sudden load drop, even when stopped to protect the  
283 generator. The time required for the power output of these systems to reach 0 kW was 64 s  
284 and 83 s, respectively “J-BG-4” had an output fluctuation: A short stoppage time of 59 s, 22 s  
285 and 2 s from the stop command to 50%, 30%, and to 0 kW of the rated output, respectively,  
286 were realized. “G-BG-1”, displayed a behavior classified in (3). It reduced its load from the  
287 stop command to 10% of the rated output in only 39 s, but continued operating at this load  
288 for about 2 min. This CHP system uses an asynchronous generator, i.e., it is always  
289 connected to the grid when operating even in the 2 min cool down phase at 10% load. Such  
290 a generator responds quickly during startup, and can be suitable for a quick shutdown, if  
291 only 90% of its capacity is defined as control reserve.

292 It was observed that the response speed of the shutdown was faster for smaller CHP systems.  
293 The shutdown characteristics defined by (1) protect the CHP system from ramp load  
294 fluctuations best, followed by those defined by (3) and (2).

295 “G-NG-2” had a quick shutdown time of 109 s due to the small size of the engine while  
296 “G-NG-1” took 26 s to shut down, but still representing a short shutdown time, considering  
297 the size difference of the engine.

298

#### 299 3.1.4 Step response characteristics

300 Fig. 7 shows the rate of change when the value of issued command is increased by  
301 increments of 10% starting from minimum output of 50%. The results represent the mean  
302 values from the start command until the unit reaches the new set-point. The electric output  
303 was measured in 1 s intervals.

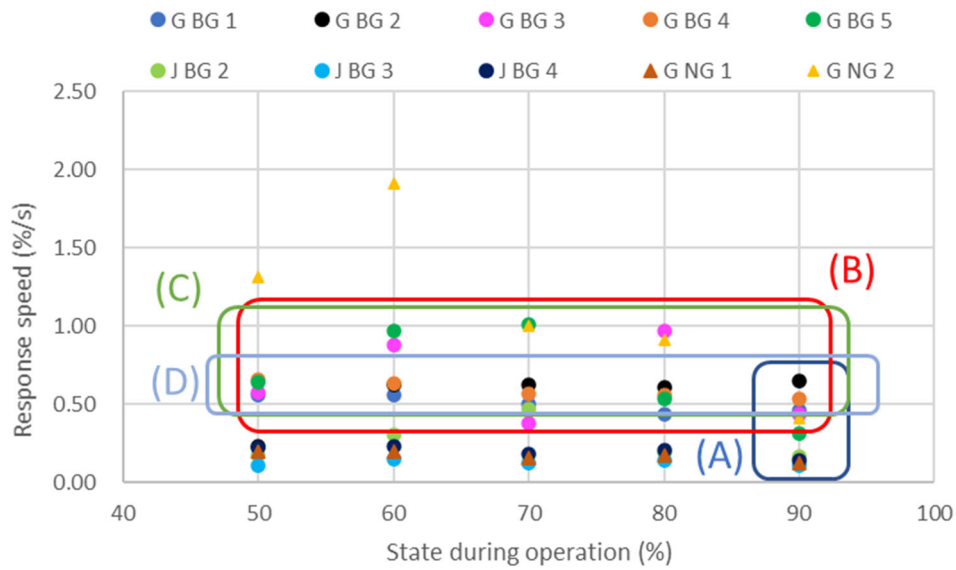

Fig.7 Step responses (Increase output by 10%)

\*1 BG: Biogas CHP  
 \*2 NG: Natural gas CHP

Fig. 8 shows the rate of change when output values are decreased by factors of 10% starting from rated output.

Fig.8 Step responses (decrease output by 10%)

\*1 BG: Biogas CHP  
 \*2 NG: Natural gas CHP

317 Fig. 7 and 8 help us evaluate the response characteristics of the biogas CHP systems. The  
 318 horizontal axis depicts the ratio to the rated output (utilized output) and represents the  
 319 operating state (output before change) at the time of issuing the command. The vertical axis  
 320 is the output change rate (%/s) based on the rated capacity of each CHP system. Fig. 7 and  
 321 8 show that the larger the absolute value of output change rate for each 10% output step, the  
 322 better the response characteristics.

323 As per Fig. 7, when the output was changed from the 90% state to the rated output (A),  
 324 there was no clear difference in response speed among all CHP systems which was found to  
 325 be between 0.11 %/s and 0.65 %/s. The German CHP systems showed high response  
 326 characteristics with increasing output (B). The German systems achieved an average  
 327 response speed of 0.50 %/s to 0.69 %/s, while the Japanese systems achieved 0.13 %/s to  
 328 0.26 %/s. The Japanese systems showed a stable response speed regardless of output band.  
 329 Of the German CHP systems, "G-BG-5" showed a particularly fast response characteristic  
 330 when the output was changed from the 60 % (0.97 %/s) to 70 % (1.01 %/s) (C). "G-BG-1"  
 331 and "G-BG-4" generally showed stable response characteristics regardless of the operating  
 332 state at the time the command was issued (D).

333 It can be seen from Fig. 8, that the Japanese systems took longer to respond than German  
 334 systems when the output was decreased (E). The average response speed over all 10 % steps  
 335 was found to be between -0.27 %/s and -0.14 % /s. The values for the German systems were  
 336 between -1.05 %/s and -0.46 %/s. "G-BG-1", "G-BG-4" and "G-BG-2", which exhibited  
 337 stable response characteristics when the output was increased, also exhibited a stable  
 338 response characteristic when it was decreased. These CHP systems had a fast response  
 339 characteristic (F).

340 "J-BG-2", "J-BG-3" and "J-BG-4" are German-manufactured CHP systems, but this test  
 341 confirms that the systems do not show the same high response and flexibility as the German  
 342 CHP systems. The average response speed of natural gas CHP systems of the same  
 343 manufacturer ("J-BG-2" to "J-BG-4") is low (0.17 %/s). "G-NG-1" was set at the minimal  
 344 responsiveness setting to provide SCR on the power control market in Germany.

345 We focused on biogas CHP systems of the same manufacturer with different models,  
 346 "G-BG-2" and "G-BG-4," and compared the response speed of output change (Table 2).

347

348 Table2 compared the response speed of output change

Output width		(unit: %/s)	
		G BG 2	G BG 4
		2006	2018
-50%		-0.59	-0.57
-20%		-0.61 (80%) * ~-0.59 (100%) *	-0.59 (80%) * ~-0.55 (100%) *
-10%	the fastest	-0.59 (70%, 80%) *	-0.54 (100%) *
	the latest	-0.68 (100%) *	-0.60 (60%) *
10%	the fastest	0.65 (90%) *	0.66 (50%) *
	the latest	0.23 (50%) *	0.53 (90%) *
20%		0.59 (60%) * ~-0.60 (80%) *	0.56 (60%) * ~-0.57 (80%) *
50%		0.58	0.56

\* State during operation

349

350

351

352 With increasing output, the speed of the response of "G-BG-2" was 0.65 %/s at its fastest  
 353 point at a 90% output state. In contrast, the response was the slowest (0.23 %/s) at 50 % of  
 354 rated output. "G-BG-2" showed a high flexibility for small output changes near the rated  
 355 output but tended to have low flexibility near the minimum output regardless of the width of  
 356 the output change. On the contrary, "G-BG-4" had the fastest response speed at the lowest  
 357 output of 0.66 %/s, showing high flexibility; it also showed a response speed of 0.53 %/s  
 358 from 90% output state to rated power, which is more than twice that of "G-BG-2"  
 359 (0.23 %/s). When output decreased, "G-BG-4" was generally faster than "G-BG-2," and the  
 360 response speed was almost constant regardless of the operation state. Thus, "G-BG-4" was  
 361 found to have improved flexibility during partial load operation compared to "G-BG-2." This  
 362 is consistent with the fact that the concerned company has recently been aggressively  
 363 pursuing development to improve the responsiveness and flexibility of power generation  
 364 output.

365 Our results correspond well with a previous study by Bär et.al. [36]. They investigated the  
 366 potential of balancing intermitted power from PV with biogas CHP units. The study  
 367 concluded that maximum ramp rates of 0.66 %/s and minimum ramp rates of 0.33 %/s  
 368 should be considered to compensate fluctuations in PV power depending on the distribution  
 369 grid [36].

370 The natural gas CHP system "G-NG-1" showed very consistent response times for all load  
 371 increments with values ranging between 0.16 %/s and 0.20 %/s. The response times are  
 372 similarly consistent with decreasing load. "G-NG-2" showed very high responsiveness for

373 both increasing and decreasing load (50% and 60%). The responsiveness of this CHP  
 374 system decreased as it got closer to full load.

375

### 376 3.2 Environmental Impact Assessment of load response

377 Exhaust-gas composition is influenced by the catalytic method for exhaust-gas purification  
 378 installed in each CHP system [19]. Only “G-BG-2” adopted a TPC system. “G-NG-2” is a  
 379 stoichiometric operated engine and therefore uses a three-way catalyst. All other biogas  
 380 CHP systems used oxidation catalyst systems. To evaluate the effect of the load response on  
 381 the exhaust emissions, steps of 10% load were observed. The measurements represent value  
 382 of the exhaust-gas components for each operating condition. CO emissions were very low  
 383 when the oxidation catalyst was new, and the operational load of the CHP system did not  
 384 affect the emissions (Fig. 9).

385

386 Fig.9 The CO emissions during step responses

387 \*1 BG: Biogas CHP

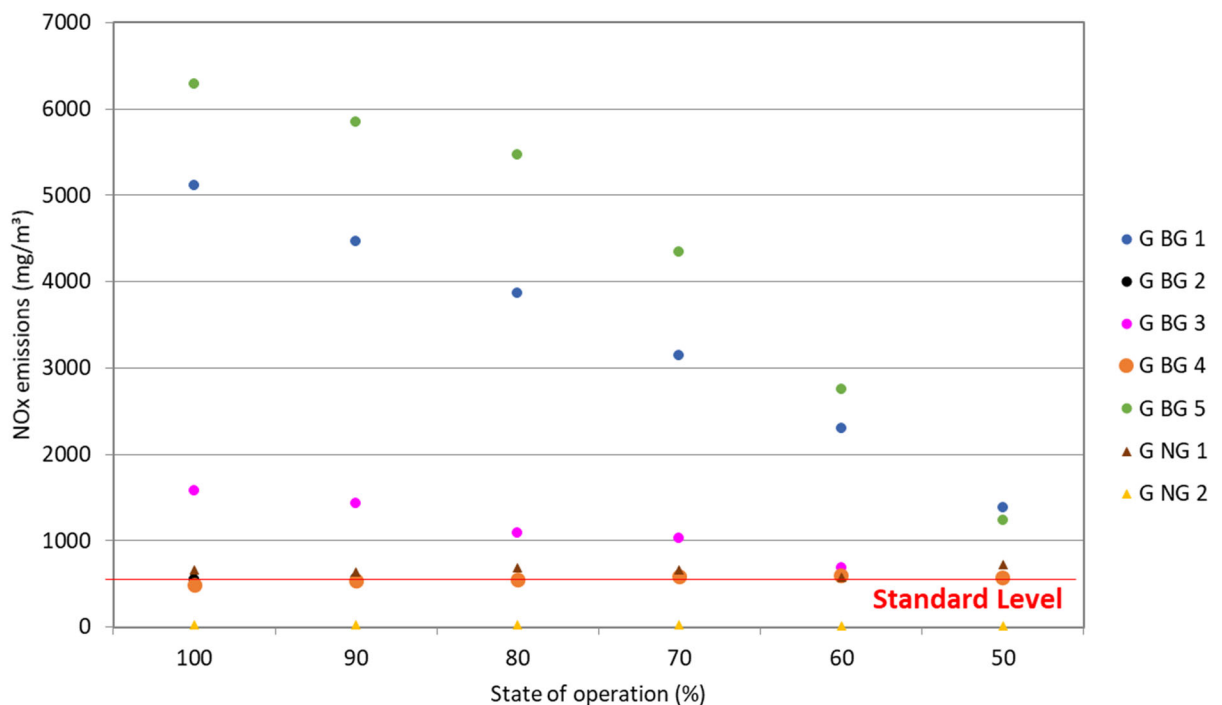

388 \*2 NG: Natural gas CHP

389

390 This result is supported by those of the CHP systems “G-BG-1,” “G-BG-3,” and “G-BG-4,”  
 391 which were equipped with an oxidation catalyst (Fig. 4). However, “G-BG-5” had the  
 392 highest CO emissions at the minimum output (50% load operation) because of the old  
 393 oxidation catalyst. At partial load, the conditions in the engine (e.g., cylinder pressure and  
 394 temperature) are not as high as at the rated output operation, resulting in an incomplete

395 combustion of engine-fuel and higher CO emissions in exhaust gas. When the oxidation  
 396 catalyst was older its performance decreased, resulting in higher CO emissions, as seen with  
 397 “G-BG-5.” At the rated load, CO emissions were the lowest due to complete combustion of  
 398 the engine fuel. The thermal post combustion system (TPC) maintains low CO emissions  
 399 regardless of the operating state of the CHP system. The CHP system operating a three-way  
 400 catalyst (“G-NG-2”) showed consistently low CO emissions at the rated load and a small  
 401 peak at partial load. The performance of this kind of catalyst is influenced by the air-to-fuel  
 402 equivalence ratio of the engine, which can deviate slightly when adjusting the load. All  
 403 examined CHP units were within the regulatory limit for CO emissions when operating at  
 404 full load [35]. Only “G-BG-5” exceeded the limit at partial load due to the old oxidation  
 405 catalyst. NO<sub>x</sub> emissions were highest during rated output operation regardless of the catalyst  
 406 type when no NO<sub>x</sub> control system was installed (Fig. 10).

407

408 Fig.10 The NO<sub>x</sub> emissions during step responses

409 \*1 BG: Biogas CHP

410 \*2 NG: Natural gas CHP

411 This is due to the “thermal-NO<sub>x</sub>” mechanism, where NO<sub>x</sub> forms due to high combustion  
 412 temperatures in the engine. Although the catalytic method of an oxidation catalyst does not  
 413 affect NO<sub>x</sub> emissions, CHP systems “G-BG-1”, “G-BG-3” and “G-BG-5” have NO<sub>x</sub> control  
 414 systems installed. The emissions were controlled at approximately 500 mg/m<sup>3</sup> regardless of  
 415 operating conditions. Here the excess air ratio of the engine is controlled based on the

416 measured  $\text{NO}_x$  in the exhaust-gas. A study showed that the excess air ratio has a direct effect  
 417 on the  $\text{NO}_x$  emissions. However, while increasing the excess air ratio results in a decrease in  
 418  $\text{NO}_x$  emissions, it comes with a loss of efficiency for the CHP system [30].

419 The TPC system (“G-BG-2”) showed almost constant  $\text{NO}_x$  emissions regardless of the  
 420 operating conditions due to the use of a  $\text{NO}_x$  control system. “G-NG-2” exhibited the lowest  
 421  $\text{NO}_x$  emissions since it used a three-way catalyst. All CHP units with  $\text{NO}_x$  control systems  
 422 (“G-BG-1”, “G-BG-3” and “G-BG-5”) were within the limit of the emissions standard of  
 423  $500 \text{ mg/m}^3 \text{ NO}_x$  [19] while those with none exceeded the limit.

424 The  $\text{CH}_4$  emissions in the biogas CHP units employing oxidation catalyst systems were  
 425 lowest during rated output operation and increased with reduced output due to incomplete  
 426 combustion engine-fuel (Fig. 11).

427

428 Fig.11 The  $\text{CH}_4$  emissions during step responses

429 \*1 BG: Biogas CHP

430 \*2 NG: Natural gas CHP

431

432 The oxidation catalyst has no influence on  $\text{CH}_4$  emissions resulting in the high emissions at  
 433 partial load. In TPC systems, extremely low  $\text{CH}_4$  emissions were observed regardless of the  
 434 operating conditions. “G-NG-2” showed very low  $\text{CH}_4$  emissions due to a naturally aspirated  
 435 engine with low power output efficiency resulting in high exhaust-gas temperatures, at  
 436 which the three-way catalyst has optimal operational temperature to convert  $\text{CH}_4$  emissions

437 with a higher performance. There are currently no emissions standard for methane  
 438 emissions in Germany. However, an emissions standard for total hydrocarbons will be  
 439 introduced in 2025 for stationary combustion engines with an electric output of over 1 MW  
 440 [32].

441 In CHP systems with new oxidation catalysts, formaldehyde emissions were generally low  
 442 regardless of the operational load (Fig. 12). All CHP systems were within in prescribed limit  
 443 of 20 mg/m<sup>3</sup> [32], apart from “G-BG-5” which exceeded the limit, especially at part load.

444  
 445 Fig.12 The formaldehyde emissions during step responses

446 \*1 BG: Biogas CHP

447 \*2 NG: Natural gas CHP

448

449 The old oxidation catalyst used by “G-BG-5” was not as effective at reducing these  
 450 formaldehyde emissions. Here, higher formaldehyde emissions were observed, especially at  
 451 partial load, due to the incomplete combustion of engine fuel. The TPC system showed  
 452 extremely low formaldehyde emissions regardless of operating conditions. Formaldehyde  
 453 emissions of “G-NG-2” were very low for all operational loads. No clear relationship was  
 454 observed between SO<sub>2</sub> emissions and power output. SO<sub>2</sub> depends on the sulfur content in  
 455 biogas, which is thought to have been affected by the desulfurization capacity before flowing  
 456 into the engine of the CHP system.

457 From these results, a TPC system is very effective for the exhaust-gas of biogas CHP units

458 regarding CO, CH<sub>4</sub> and formaldehyde. Additionally, NO<sub>x</sub> can be controlled using a Lambda  
 459 control system. However, such a TPC system has high investment and operating costs, and  
 460 high demand for installation space.

461 An oxidation catalyst is effective for CO and formaldehyde, because these catalysts have  
 462 been optimized for operation due to existing German emissions standards. It affects NO<sub>x</sub>  
 463 and CH<sub>4</sub> emissions only slightly at higher temperatures, however the lower investment and  
 464 operating costs of such a catalyst make it an attractive option if there is no emission standard  
 465 for CH<sub>4</sub>. However, the results show that the performance of oxidation catalysts decreases  
 466 over time resulting in higher CO and formaldehyde emissions at the end of its lifespan.

467 Three-way catalysts have a high potential for converting CO, NO<sub>x</sub>, CH<sub>4</sub> and formaldehyde.  
 468 However, these types of catalysts can only be applied to stoichiometric operated engines and  
 469 require exact control of the air-to-fuel equivalence ratio of the engine.

470

### 471 3.3 Environmental Impact Assessment of startup and shutdown

472 The startup and shutdown of the engine had an impact on the exhaust emissions of biogas  
 473 CHP systems. Parameters were unchanged from the standard stationary operations.

474 In terms of the CO emissions of the biogas CHP systems during startup, no peak was  
 475 observed for the systems with new oxidation catalysts (“G-BG 1” and “G-BG-3”) (Fig. 13).

476

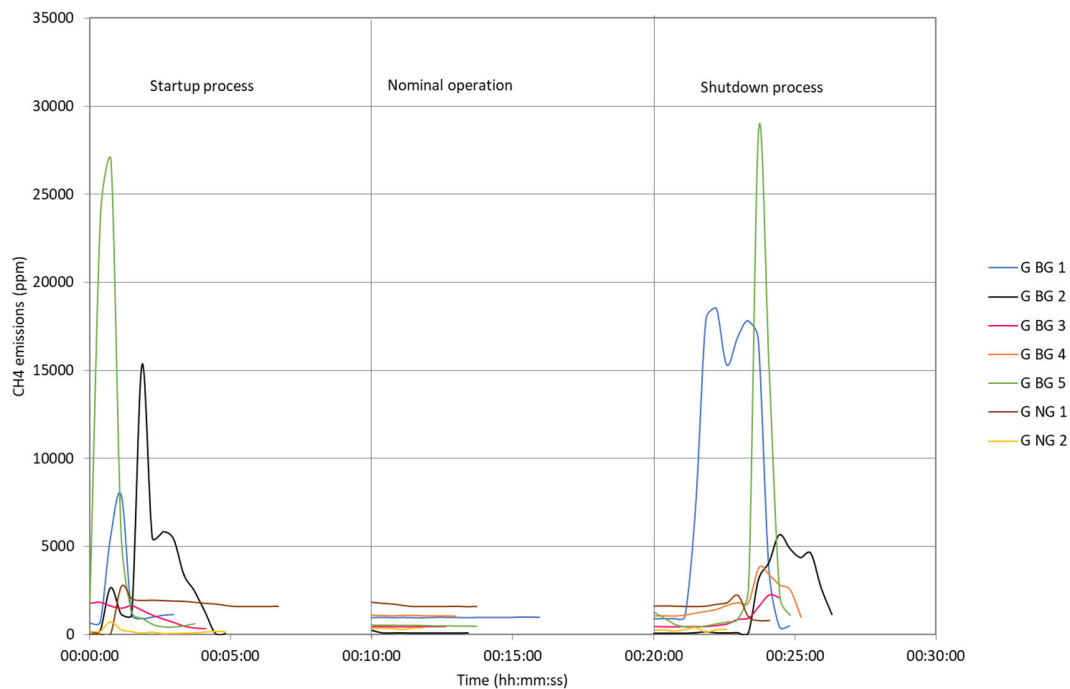

477 Fig.13 The CO emissions during startup and shut down

478 \*1 BG: Biogas CHP

479 \*2 NG: Natural gas CHP

480

481 However, the system with the old oxidation catalyst (“G-BG-5”) had a distinctive maximum  
 482 during the startup process. During shutdown of the engine peaks, CO emissions were  
 483 observed for both the new (“G-BG-3” and “G-BG-4”) and the old (“G-BG-5”) oxidation  
 484 catalyst systems. Only one CHP system with a new oxidation catalyst (“G-BG-1”) showed  
 485 no maximum during shutdown. The natural gas CHP unit “G-NG-1” showed consistently  
 486 low CO concentrations during startup and shutdown due to the installation of a brand-new  
 487 oxidation catalyst. The other natural gas CHP system with a three-way catalyst, “G-NG-2,”  
 488 showed a peak in CO at startup but none during shutdown. Similar behavior was observed  
 489 for the biogas and natural gas CHP systems in terms of CH<sub>4</sub> and formaldehyde emissions  
 490 (Fig. 14 and 15).

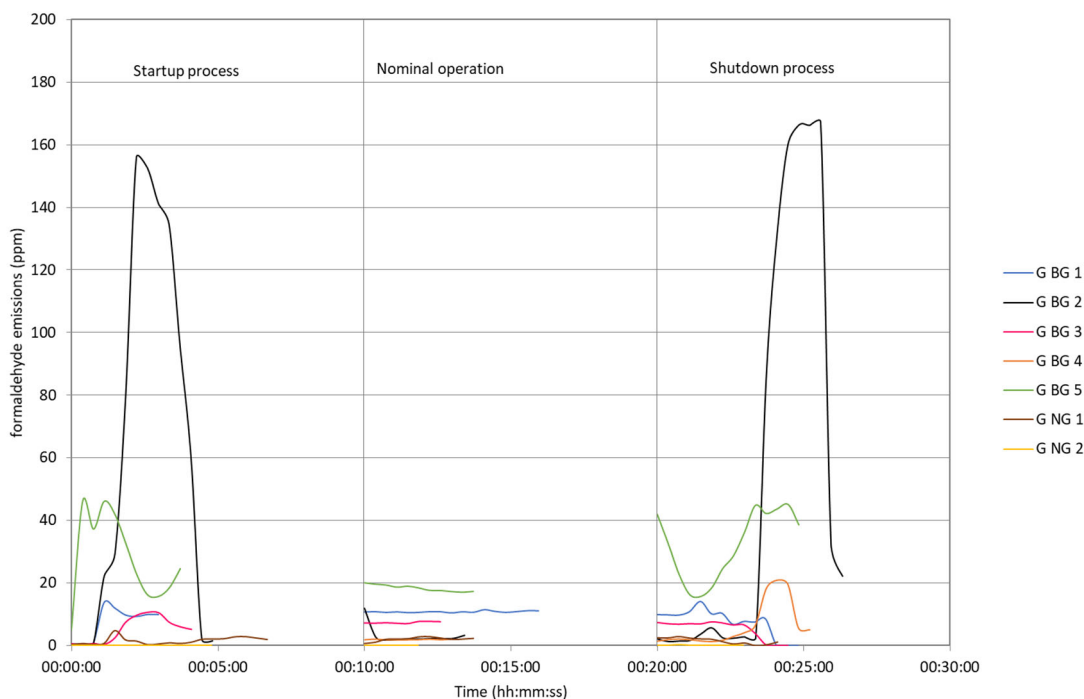

491

492 Fig.14 The CH<sub>4</sub> emissions during startup and shut down

493 \*1 BG: Biogas CHP

494 \*2 NG: Natural gas CHP

495

496

Fig.15 The formaldehyde emissions during startup and shut down

497 \*1 BG: Biogas CHP

498 \*2 NG: Natural gas CHP

499 During engine startup, all systems with oxidation catalysts showed a brief maximum of  $\text{CH}_4$   
 500 and formaldehyde emissions before decreasing during normal operation. On shutdown,  
 501 distinctive peaks in  $\text{CH}_4$  could be seen but formaldehyde emissions were not as high.

502 The operation of the TPC system (“G-BG-2”) demonstrated differing behavior in terms of  
 503 CO,  $\text{CH}_4$  and formaldehyde emissions. The TPC system was in standby operation on engine  
 504 startup. Hence, high concentrations of CO,  $\text{CH}_4$  and formaldehyde could be measured. The  
 505 TPC system began operation towards the end of the engine startup process resulting in  
 506 decreasing concentrations of CO,  $\text{CH}_4$  and formaldehyde in the exhaust-gas. The natural gas  
 507 system “G-NG-2” showed low  $\text{CH}_4$  emissions during startup and shutdown.

508 The  $\text{NO}_x$  emissions are not dependent on the oxidation catalyst system or fuel used  
 509 (Fig. 16).

510

511

Fig.16 The NO<sub>x</sub> emissions during startup and shut down

512 \*1 BG: Biogas CHP

513 \*2 NG: Natural gas CHP

514

515 The emissions can differ between biogas CHP systems with NO<sub>x</sub> control systems  
 516 (“G-BG-2”, “G-BG-3” and “G-NG-1”) and those without (“G-BG-1” and “G-BG-5”). The  
 517 NO<sub>x</sub> emissions of all engines rose steadily until rated operation was attained. The CHP  
 518 systems without NO<sub>x</sub> control systems then stayed at this level during stationary operation.  
 519 With installation of a NO<sub>x</sub> control system, the lambda of the engine increases after reaching  
 520 rated operation until the NO<sub>x</sub> emissions reach 500 mg/m<sup>3</sup>. During shutdown, the NO<sub>x</sub>  
 521 emissions reduce steadily regardless of a NO<sub>x</sub> control system being installed. The CHP  
 522 system “G-NG-2” uses a three-way catalyst that can only be used for stoichiometric operated  
 523 engines and can also reduce NO<sub>x</sub> emissions. Small peaks in NO<sub>x</sub> were seen during startup  
 524 and shutdown of “G-NG-2” due to some residual oxygen in the exhaust-gas that reduces the  
 525 performance of the three-way catalyst.

526 SO<sub>2</sub> emissions were observed during both, startup and shutdown of the engines but were  
 527 observed to be independent of the startup or shutdown. Low concentrations of SO<sub>2</sub> were  
 528 measured regardless of the load when sulfur concentrations were observed in the biogas

529 while no SO<sub>2</sub> concentrations were measured for either natural gas CHP system.  
530 The above results show that a TPC system can reduce CO, CH<sub>4</sub> and formaldehyde emissions  
531 effectively. However, high concentrations of the exhaust components could be measured  
532 during the startup and shutdown process before the TPC system was in full operation. Cold  
533 startup processes of the TPC were not considered for this study. The TPC systems generally  
534 have startup processes that take several hours when initially starting operation after longer  
535 shutoff periods. In this study a “warm” startup was considered when the engine was shutoff  
536 for only some minutes with the TPS system in standby operation.

537 Oxidation catalysts can help reduce CO and formaldehyde emissions during startup and shut  
538 down but have little influence on CH<sub>4</sub> emissions. The older the oxidation catalyst, poorer is  
539 its performance. NO<sub>x</sub> emissions are generally high during startup. If a NO<sub>x</sub> control is  
540 installed, then its concentrations are decreased after startup. The shutdown process does not  
541 influence NO<sub>x</sub> emissions significantly. If a stoichiometric operated engine is considered, a  
542 three-way catalyst can not only reduce CO, CH<sub>4</sub> or formaldehyde emissions during  
543 stationary operation, but also that of NO<sub>x</sub>. However, such a catalyst performs poorly when  
544 small amounts of residual oxygen are present in the exhaust-gas, e.g. during startup and  
545 shutdown due to the sensitive nature of the lambda control. The emissions were generally  
546 found to be lower or equal for a three-way catalyst in comparison to an oxidation catalyst.

547

#### 548 4. Conclusions

549 Assuming that a biogas CHP system is used as a new supply-demand adjustment resource  
550 for mitigating output fluctuations in variable renewable energy, it can contribute to a  
551 long-term adjustment power equivalent, such as SCR or TCR in Germany. The current state  
552 of the art is suitable for SCR with start-up and shut-off times of under 5 minutes. In the  
553 current Japanese power market, responsiveness and flexibility of biogas CHP systems are not  
554 essential, but in the future, the requirements for adjustment capability will be categorized  
555 based on responsiveness [37]. However, to operate efficiently, it is necessary for the biogas  
556 CHP system to equip a biogas bag with the capacity to supply power to restore the control  
557 reserve. Many biogas plants in Japan do not have adequate gas-bag capacity due to the  
558 FIT-specification power production strategy, so an upgrade is essential to provide  
559 adjustment capacity. Since the emission of CH<sub>4</sub>, formaldehyde, and SO<sub>2</sub> increases when a  
560 CHP system starts and stops, gas-bag capacity should be designed to reduce output  
561 fluctuations. Furthermore, as the use of RE power sources continues to expand in the future,  
562 there is a concern that the supply-demand adjustment capability of the entire power source  
563 system will be insufficient. To improve the operability of the biogas CHP system, other  
564 strategies must be developed, such as increasing the response speed of output changes and

565 lowering the minimum output to increase the range of output changes.  
566 It is important to clarify the effects of differences in operational methods (normal/flexible  
567 operation) through measurement and analysis of operational data of biogas CHP systems  
568 that are connected to the grid for commercial operation. The Global Warming Potential  
569 (GWP) of flexible operation should be investigated further due to an increase of CH<sub>4</sub> and  
570 formaldehyde during startup and shutdown.

571 In the case of the German energy system, where frequency control by biogas CHP systems is  
572 already common practice, the potential for providing further ancillary services need to be  
573 investigated. These services include voltage control, provision of reactive power, congestion  
574 management, and black start capabilities. The need for such services is expected to increase  
575 as the share of renewable energy in the grid rises. Biogas presents an ideal renewable energy  
576 resource in this regard as it can easily be stored in large quantities—unlike other resources  
577 such as solar and wind energy.

578

#### 579 Acknowledgments

580 This study was conducted in collaboration with Hokuo Consultant Co., Ltd. (Obihiro,  
581 Hokkaido). Work was partially carried out within the framework of the joint research project  
582 OPTIBIOSY funded by the German Federal Ministry of Food and Agriculture, grant  
583 numbers 22410417 and 22410517. In addition, biogas CGS companies have greatly  
584 cooperated in field tests in Germany and Japan. The authors are grateful to all parties and  
585 organizations involved.
