#### 29 Abstract

30 Previous studies have indicated that prenatal exposure to dioxin-like compounds (DLC) or polychlorinated biphenyl (PCB) has a negative association with neurodevelopment in school-aged 31 32 children. Event-related brain potentials (ERP) can reveal subtle and specific differences in the 33 modulation of cognitive processes that are assumed when they are associated with lower levels 34 of prenatal exposure to DLC or PCBs. This prospective birth cohort study was conducted to 35 examine the association between prenatal exposure to relatively low levels of DLC, PCB or 36 methylmercury (MeHg), and ERP. A total of 55 children who were 13 years old participated in a 37 3-stimulus oddball task to detect P3a and P3b waves. The task required participants to respond to 38 a target among random stimuli at two difficulty levels. The P3a amplitude reflects an automated 39 attention capture process, and P3b reflects a voluntary attention allocation process. We analyzed 40 DLC congeners in blood samples from four groups, including 7 polychlorinated dibenzo-p-41 dioxins (PCDD), 10 polychlorinated dibenzofuranes (PCDF), 4 non-ortho PCBs, and 8 mono-42 ortho PCBs. PCB-153 was chosen as an indicator because of its high correlation with the sum of 43 58 NDL (non-dioxin-like)-PCBs. MeHg exposure level was assessed by the mercury 44 concentration in hair samples (HHg) taken during the perinatal period. 45 The reaction time to the target stimulus during the oddball task shortened with the increasing

46 MeHg exposure level. Furthermore, P3b latency, which reflect response decision and correlates

47	with reaction time, was also shortened with increasing MeHg level in the difficult condition.
48	These results are counterintuitive because shorter reaction times or rapid decision making
49	reflected by P3 latency are generally favorable. This might be due to nutritional factors such as
50	fatty acids, which have beneficial effects on brain development. The P3a amplitude decreased
51	with non- and mono-ortho PCB and HHg levels, regardless of the difficulty level, and with PCDD,
52	PCDF, and total DLC levels, especially in the difficult condition. P3b latency shortened with HHg,
53	and P3b amplitude decreased with mono-ortho PCBs and PCB-153 in both conditions and with
54	PCDD, PCDF, non-ortho PCBs, and total DLC in the difficult condition.
55	In conclusion, we found an association between prenatal exposure to DLC and a decrease in
56	both P3a and P3b amplitude, even when DLC levels were lower than in most previous studies.
57	Additionally, our results suggest that the automated attention capture process reflected by P3a is
58	associated with maternal MeHg exposure and that the voluntary attention allocation process
59	reflected by P3b is associated with PCB-153. However, these results should be interpreted with
60	caution because of the limitations on sample size, population bias, and statistical analyses.

62	related potential, methylmercury
63	

### 65 **1. Introduction**

66 Human exposure to persistent organic pollutants, including polychlorinated dibenzo-p-dioxins 67 (PCDDs), polychlorinated dibenzofurans (PCDFs), and polychlorinated biphenyls (PCBs) from 68 environmental sources and daily food intake is widespread (Todaka et al., 2008). Seventeen 69 PCDDs/PCDFs and 12 PCBs have been categorized as dioxin-like compound (DLC) (Van den 70 Berg et al., 2006). Mercury (Hg) is another environmental contaminant that is converted to 71 methylmercury (MeHg) in the aquatic environment and then bioaccumulated in fish, shellfish, 72 and marine mammals through the food chain. Ingestion of these seafoods is the main route of 73 MeHg exposure. Exposure to higher levels of these environmental contaminants during the 74 prenatal and neonatal periods is known to cause various toxicities, including carcinogenicity, 75 teratogenicity, endocrine, immune, and reproductive disruption, as well as neurobehavioral issues 76 (Clarkson and Magos, 2006; Todaka et al., 2010; Wigle et al., 2008). 77 There are numerous epidemiological studies regarding prenatal exposure to these contaminants 78 and child neurodevelopment, including dioxins or DLC (Ames et al., 2019; Caspersen et al., 2016; 79 Granillo et al., 2019; Hui et al., 2016; Ikeno et al., 2018; Nakajima et al., 2006, 2017; Neugebauer 80 et al., 2015; Nowack et al., 2015; Sioen et al., 2013; Ten Tusscher et al., 2014; Tran et al., 2016; 81 Winneke et al., 2014), and PCB (Berghuis et al., 2013; Bernardo et al., 2019; Boucher et al., 2012, 82 2016; Braun et al., 2014; Caspersen et al., 2016; Chu et al., 2019; Dickerson et al., 2019; Ethier

83	et al., 2015; Gascon et al., 2013; Grandjean et al., 2012; Granillo et al., 2019; Kim et al., 2018;
84	Kyriklaki et al., 2016; Nakajima et al., 2006; Nowack et al., 2015; Sioen et al., 2013; Šovčíková
85	et al., 2015; Stewart et al., 2012; Verner et al., 2015; Winneke et al., 2014). Most of these studies
86	predominantly used questionnaires or face-to-face behavioral examination to assess behavioral
87	problems, cognitive ability, or intelligence (e.g., Strength and Difficulties Questionnaire, Finger
88	tapping test, or Wechsler Intelligence Scale for Children etc.).
89	Furthermore, several previous studies have investigated the effect of neurotoxic substances on
90	cognition and attentional processing using event-related brain potential (ERP). ERP can reveal
91	subtle and specific differences in brain activity and there is accumulating evidence on variability
92	of ERP waves related to cognitive processes (Rugg & Coles, 1995). One of the most prominent
93	waves of ERP is the P3 observed during an oddball task where participants respond to (or count)
94	a target stimulus during the random presentation of a series of targets and frequent, standard
95	stimuli. The P3 elicited by the target stimuli is called "P3b"; its amplitude is considered to reflect
96	voluntary attention allocation, and its latency is interpreted as the speed of stimulus evaluation in
97	determining whether the current stimulus should be responded to (Polich & Criado, 2006; Riggins
98	& Scott, 2020). P3b has a parietal scalp distribution with a peak latency between 300-600 ms
99	from stimulus onset (Donchin, 1981; Katayama & Polich, 1996a; Sutton et al., 1965). Although
100	P3b is a part of P3, usually the term "P3" is used to mean P3b. Therefore, the term "P3" used in

101 the following previous studies can be interpreted as basically referring to P3b.

102 The association between the dioxin level in breast milk and P3 during a visual oddball task was 103 investigated in a cohort study in Amsterdam (Schellart & Reits, 2008; Ten Tusscher et al., 2014). 104 They reported that the high-exposure group had a longer P3 latency and smaller P3 amplitude 105 than the norm value calculated using a control group. 106 With respect to PCB exposure, previous studies have investigated P3 in children during an 107 oddball task. In Taiwan, Chen and Hsu (1994) reported significantly longer P3 latencies, and 108 significantly reduced amplitude in the Yu-Cheng ("oil disease") group compared to the control 109 group during an auditory oddball task. In The Netherlands, Vreugdenhil et al. (2004) also found 110 that children with high prenatal exposure to PCBs in the maternal plasma had longer P3 latencies 111 than those with low prenatal exposure; however, this did not affect the P3 amplitude. Boucher et 112 al. (2010) showed that prenatal PCB exposure was associated with a decrease in the P3b amplitude 113 in a subgroup of children who had been breastfed < 3 months. In this study, we were interested in 114 whether both PCB and DLCs were associated with P3 latency or amplitude even at low exposure 115 levels. 116 Additionally, there are nine studies regarding the association between prenatal exposure to 117 MeHg and basic perceptual processes using evoked brain potentials (Boucher et al., 2012, Ethier

118 et al., 2012, Grandjean et al., 1997, 2001a, 2001b, 2004; Murata et al., 2002, 2004b; Yorifuji et

119	al., 2013), and seven studies found some modulation in visual evoked potential or auditory
120	brainstem responses (Ethier et al., 2012, Grandjean et al., 1997, 2001a, 2004; Murata et al., 2002,
121	2004b; Yorifuji et al., 2013). Boucher et al. (2010) also reported that cord blood Hg was associated
122	with the N1 wave during oddball tasks, but not with the P3, and suggested that prenatal MeHg
123	exposure alters the attentional mechanisms modulating the early processing of sensory
124	information as reflected by N1. It is worthwhile to investigate MeHg in addition to DLC and PCB
125	exposure because ERP wave related to attentional capture process might associate with MeHg,
126	and because the exposure sources were mainly fish/seafood intake in the Japanese population
127	(Miyashita et al., 2015).
128	Although these previous studies investigated association between chemical exposure and
129	children's cognitive process using mainly P3b, the term "P3" is used to mean P3b and not included
130	P3a. To examine additional cognitive processes, we focused on another P3 elicited by non-target
131	stimuli during the 3-stimulus oddball task, which is called "P3a," and thought to reflect attentional
132	capture by the distractor stimuli (Escera et al., 1998; Friedman et al., 2001; Rushby et al., 2005;
133	Sawaki & Katayama, 2008). P3a shows a wider frontal scalp distribution, with a shorter peak
134	latency compared to P3b (Courchesne et al., 1975; Squires et al., 1975). P3a is not easily
135	detectable in the 2-stimulus oddball task but is detectable when using the 3-stimulus oddball task
136	in which non-target stimuli are presented with low probability in addition to target and standard

137	stimuli presented as in typical 2-stimulus oddball tasks (Courchesne et al., 1975; Katayama &
138	Polich, 1996b). There is a developmental difference between P3a and P3b (Fuchigami et al., 1995)
139	wherein the automatic processes indexed by P3a seem to mature earlier than the controlled
140	processes reflected by P3b (Stige et al., 2007). If P3a and P3b could be separated, it might be
141	possible to examine whether DLC and/or PCB affects the automated attention capture process
142	reflected by P3a, or the voluntary attention allocation process reflected by P3b. Therefore, we
143	aimed to explore the association between exposure to prenatal DLC, PCB, and HHg at low levels
144	and the cognitive processes indicated by P3a and P3b using a 3-stimulus oddball task which is
145	suitable for detecting P3a (Comerchero & Polich, 1999; Katayama & Polich, 1998).

## 147 **2. Methods**

# 148 2.1 Study population

This study was conducted using data from a prospective study, the Sapporo Cohort of the Hokkaido Study on Environment and Children's Health (Kishi et al., 2011, 2013, 2017, 2021). In brief, we recruited 514 pregnant women from the Sapporo Toho Hospital in Hokkaido, Japan, between July 2002 and July 2005. All participants were native Japanese women, residing in Sapporo and surrounding areas. The participants completed a self-administered questionnaire after the second trimester of their pregnancy, with baseline information such as educational level, family income, tobacco/smoking history, and alcohol consumption. Clinical perinatal data of mothers and infants were collected from the participants' medical records. To obtain information on maternal fish intake throughout pregnancy, participants were contacted within 5 days of delivery. Participants also provided a hair sample for mercury measurements and information on their history of having their hair permed.

160 Invitation letters were sent to 293 children who could be followed up and were living close to 161 Sapporo city at the time of ERP recording (11-14 years old) among the initial 514 participants. 162 Ninety-three pairs of mothers and children agreed to participate in ERP recordings. Thirteen 163 participants who participated in preliminary test recordings, seven who had a developmental 164 disorder diagnosis (3 with pervasive developmental disorder, 1 with Asperger syndrome, 1 with 165 attention deficit hyperactivity disorder, 2 with unidentifiable disorder), and two lacking DLC or 166 PCB data were excluded. Of the remaining 71, ERP data from 16 participants who had excessive 167 eye blinking or noise in either experimental condition were not included (Luck, 2014). Finally, 168 data from 55 participants with complete ERP, DLC, and PCB data were included in the analysis. 169 The flowchart of participant recruitment and data selection is shown in Figure 1. 170 The protocol for this study was approved by the Ethics Review Board for Epidemiological 171 Studies at the Hokkaido University Graduate School of Medicine and the Hokkaido University 172 Center for Environmental and Health Sciences (14-10-1) and was conducted in accordance with the principles of the Declaration of Helsinki. All mothers and children who participated in the

175 176 Pregnant women were enrolled. Jul.2002-Oct.2005 (n = 514) 177 Agreement for face-to-face examination at registration (n = 329) 36 participants were excluded because their residence was too distant 178 from the ERP recording location (Hokkaido University). Invitation letter for ERP recording was sent. 2017-2018 (n = 293) 179 Agreement for ERP recording (n =93) Excluded participants 180 -13 participants whose data was recoded in preliminary test recording -7 participants with a developmental disorder diagnosis (3 with pervasive developmental disorder, 1 with Asperger syndrome, 1 with attention deficit hyperactivity disorder, 2 with unidentifiable disorder), 181 -2 participants lacking DLC or PCB data -16 participants had ERP data with too much eyeblink or noise (data from participants whose number of averaged trials < 10 was excluded) 182 Data used for statistical analysis in this study (n = 55)

183 Figure 1. Flowchart of participant recruitment and data selection.

ERP recording provided written informed consent.

184 ERP, event-related brain potential; DLC, dioxin-like compound; PCB, polychlorinated biphenyl

185

174

186 2.2 Exposure assessment

187 A 40 mL blood sample was collected from the maternal peripheral vein in the last trimester, except

- 188 in those subjects with pregnancy-related anemia, from whom blood samples were collected
- 189 immediately after delivery (16 among 55 included participants). All blood samples were stored at
- 190 -80°C. Non-dioxin-like (NDL)-PCB, PCDD/PCDF, and DL-PCB levels in the maternal blood
- 191 were assessed with high-resolution gas chromatography/high-resolution mass spectrometry

192	equipped with a solvent-cut large-volume injection system at the Fukuoka Institute of Health and
193	Environmental Sciences, as previously described (Iida and Todaka, 2003; Todaka et al., 2003,
194	2008). NDL-PCB, PCDD/PCDF, and DL-PCB levels have been described in our previous study
195	(Miyashita et al., 2015) and were adjusted by total lipid content (pg/g lipid) (Todaka et al., 2003).
196	Toxic equivalent (TEQ) values were calculated by multiplying the concentration of the individual
197	congener of PCDDs/PCDFs and DL-PCBs by its specific toxic equivalency factor value (Van den
198	Berg et al., 2006). Values below the detection limit were assigned as 50% of the detection limit.
199	Finally, 58 NDL-PCBs, 12 DL-PCBs, and 17 PCDD/PCDF congeners were analyzed in 426 blood
200	samples. DLC congeners were categorized into four DLC groups, including 7 PCDDs, 10 PCDFs,
201	4 non-ortho PCBs, and 8 mono-ortho PCBs. PCB-153 was chosen as an indicator because it had
202	a high correlation with the sum of 58 NDL-PCBs (Pearson's correlation coefficient = 0.97, p <
203	0.01). MeHg exposure in utero was estimated from total HHg concentration in the maternal hair
204	(Joint FAO/WHO Expert Committee on Food Additives (2003: Rome, Italy), World Health
205	Organization & Food and Agriculture Organization of the United Nations, 2004). Total mercury
206	concentrations were determined in 1 cm hair segments closest to the scalp (0.7–1.2 mg) using the
207	oxygen combustion-gold amalgamation method using a MD-1 atomic absorption detector
208	(Nippon Institute, Co., Ltd., Osaka, Japan) at the National Institute for Minamata Disease, as
209	previously described (Yasutake et al., 2003).

211 2.3 ERP procedure

212 ERPs were recorded during the 3-stimulus visual oddball task. Two conditions, which 213 manipulated the difficulty of target/standard identification were implemented because P3a is 214 larger and easier to detect when for difficult tasks compared to the waveform during easy 215 conditions (Comerchero & Polich, 1999; Katayama & Polich, 1998). During the experiment, the 216 child sat at a viewing distance of 1 m from a computer screen. The standard (70% presentation 217 probability), target (15%), and non-target (15%) stimuli were visually presented in a random 218 series, once every 2 s for a 300 ms duration on a gray background using E-Prime (E-Prime 2.0, 219 Psychology Software Tools Inc., Pittsburgh, PA, USA). Figure 2 summarizes the stimuli used in 220 this study. The standard stimulus was a blue circle  $(0.23^{\circ} \times 0.23^{\circ}, 40 \text{ mm in diameter})$  in both 221 conditions. The target stimulus was a small blue circle  $(0.16^{\circ} \times 0.16^{\circ}, 28 \text{ mm in diameter})$  for 222 easy tasks and a blue circle  $(0.21^{\circ} \times 0.21^{\circ}, 36 \text{ mm in diameter})$  slightly smaller than the standard 223 blue circle for difficult tasks. The non-target stimulus was a square  $(0.23^{\circ} \times 0.23^{\circ}, 40 \text{ mm on each})$ 224 side). The child was asked to respond to the target stimuli by pushing a button with the right 225 thumb as quickly as possible, and to ignore standard or non-target stimuli. The target stimulus 226 elicits larger P3b compared to the ERP triggered by the standard stimulus, and the non-target 227 stimulus elicits larger P3a especially in the difficult condition according to previous studies

(Comerchero & Polich, 1999; Katayama & Polich, 1998). In each condition, there were four blocks consisting of 100 trials each, as well as one practice block at the beginning. The participants could rest between blocks to minimize the influence of motivation and fatigue.

	Target (15%)	Standard (70%)	Non-target (15%)
Easy			
Difficult			
Figure 2. Stimuli u	used in the oddball ta	sk	
2.4 ERP Recordir	ng and Analysis		

Electroencephalograms (EEGs) were recorded from four midline scalp sites (Fz: frontal, Cz: central, Pz: parietal, and Oz: occipital) according to the 10-20 system and from the earlobes by referring to the nose tip, with the forehead as ground and impedance at  $\leq 10 \text{ k}\Omega$  using the MaP2260 system (NIHON SANTEKU Co., Ltd, Osaka, Japan). Additional electrodes were placed at approximately 1 cm from the upper right eye and below the left eye to monitor electrooculogram

<sup>(</sup>EOG) activity with bipolar recording. The signals were digitized online at a rate of 1000 Hz with

a low-pass filter at 100 Hz and high-pass filter at 0.053 Hz. A 30 Hz low-pass filter was applied

<sup>242</sup> for all data offline, and the EEGs were re-referenced by averaged earlobes. Waveforms were

<sup>243</sup> averaged offline for 800 ms with a 200-ms pre-stimulus baseline, such that trials with a response

244	error or those where the EEG or EOG > $\pm75$ µV were rejected automatically. Data from
245	participants who had <10 trials within the rejection criteria for any condition were not included.
246	Eventually, 55 participants who had complete ERP data were included in the analysis.
247	The P3 component was defined as the largest positive peak occurring within the 300-600 ms
248	latency window. To calculate the mean amplitudes, P3a peak at Cz were identified as 369 ms in
249	the easy condition and 396 ms in the difficult condition on grand-averaged ERP waveforms, and
250	P3b peaks at Pz were as 435 ms and 514 ms, respectively. These electrode sites were chosen for
251	analyses a priori, with reference to previous studies (Katayama & Polich, 1996a, b; 1998; Polich
252	& Criado, 2006; Sawaki & Katayama, 2008). Subsequently, the mean amplitudes within the $\pm$ 50
253	ms range of peak latencies were calculated for P3a (319 -419 ms in the easy condition, 346-446
254	ms in the difficult condition) and P3b (385-485 ms in the easy condition, 464-564 ms in the
255	difficult condition) at Fz, Cz, Pz, and Oz on each participant's individual ERP waveforms
256	automatically. For regression analysis, the mean amplitude and peak latency at Cz when the non-
257	target stimulus was presented were designated as P3a, and the mean amplitude and peak latency
258	at Pz when the target stimulus was presented were designated as P3b. ERP analysis was
259	implemented using EEGLAB version 14 (http://www.sccn.ucsd.edu/eeglab, Delorme and Makeig,
260	2004) running under MATLAB 9.5.0 (The MathWorks, Natick, MA, USA).
261	

## 262 2.5 Data analysis

263 The characteristics of the participant group and the other participants of the cohort (defined as 264 non-participant group) were initially analyzed using the chi-square test and Student's t-test. The 265 DLC (Sub-total PCDD, Sub-total PCDD, Sub-total non-ortho PCBs, Sub-total mono-ortho PCBs), 266 PCB (PCB-153), and mercury concentration in hair samples (HHg) were compared between 267 participants and non-participants using the Mann-Whitney U test. DLC, PCB and HHg values 268 were log10 transformed since the exposure level of these contaminants shows log-normal 269 distributions. For the oddball task performance, omission errors, false alarms, and reaction times 270 across conditions were compared using paired-sample t-tests. The omission error rate indicates 271 the prevalence of missing to press the button to the target stimulus, false alarm rate indicates the 272 prevalence of button press to the standard stimulus. The hit reaction time is the mean of time from 273 stimulus presentation to the button press to the target stimulus. These behavioral measures can 274confirm whether subjects performed the task properly and whether the task difficulty condition 275 worked as intended. 276 P3a and P3b latency and mean amplitude were assessed using repeated measures analysis of 277 variance (ANOVA). Greenhouse-Geisser correction was applied to the degrees of freedom in

ANOVA, when appropriate. Post-hoc comparisons were performed using the Bonferroni procedure when a significant main effect of the electrode or any interaction was obtained.

280	Multiple regression analysis was performed to examine the association of DLC, PCB, or HHg
281	concentrations with behavior or P3a/b during the oddball task. Potential confounders were
282	selected based on previous studies (Boucher et al., 2010; Miyashita et al., 2015; Schellart & Reits,
283	2008; Vreugdenhil et al., 2004). Subsequently, directed acyclic graphs (DAGs) were used to
284	determine the adjustment factors (Supplemental Figure 1). The set of variables selected for
285	adjustment were maternal age, smoking during pregnancy, and being first-born or not. However,
286	the smoking status during pregnancy could not be considered because there were only three
287	smoking mothers among our participants. The breastfeeding period (Boucher et al., 2010;
288	Vreugdenhil et al., 2004) and age at the time of ERP examination (Schellart & Reits, D., 2008)
289	were included a priori because both were crucial for ERP. The blood sampling period was also
290	included for the DLC, PCB models. To facilitate interpretation of the study results, post hoc power
291	analysis was conducted using G* Power3 software (Faul et al., 2007). In the multi-regression
292	analysis with six predictors for the DLC, PCB models (exposure, maternal age, smoking during
293	pregnancy, being first-born, breastfeeding duration, age at examination, and blood sampling
294	period), the detectable effect size f 2 was 0.28 (n = 55, $\alpha$ = 0.05, $\beta$ = 0.2); in the analysis with five
295	predictors for the HHg model, where the predictors were the same as in the s model except for
296	the blood sampling period, the detectable effect size f 2 was 0.26 n = 55, $\alpha$ = 0.05, $\beta$ = 0.2).
297	According to Cohen's guidelines (1988), f $2 \ge 0.02$ , f $2 \ge 0.15$ , and f $2 \ge 0.35$ represent small,

medium, and large effect sizes, respectively. Therefore, our analysis could detect a medium to
large effect size. The significance level was set at p < 0.05. All statistical analyses were performed</li>
using SPSS version 22.0. (SPSS, Chicago, IL, USA).

**3. Results** 

*3.1 Descriptive statistics* 

304	The basic characteristics of the study population are summarized in Table 1. The average
305	maternal age at delivery was $32.9 \pm 4.2$ years (mean $\pm$ standard deviation [SD]) and paternal age
306	was $35.0 \pm 5.8$ years. Most of the mothers had an education > 13 years (72.7%) and did not smoke
307	during pregnancy (94.5%). Among the infants, 47.3% were male, 49.1% were first-born, and
308	14.5% had breastfeeding for $>$ 3 months. Comparing the characteristics of participant included in
309	the analysis and non-participant groups who were the other participants of the cohort, participants
310	had higher maternal and paternal ages, higher education level, and lower smoking rate.
311	Additionally, the prevalence of children who were breastfed for $> 3$ months was lower.
312	Maternal serum DLC, PCB, and HHg concentrations are shown in Table 2. PCDD, non-ortho
313	PCBs, mono-ortho PCBs, total DLC, and PCB-153 were significantly higher, and PCDF was
314	marginally higher but significant in the participant than in the non-participant group. HHg levels
315	did not differ between groups.

# 330 Table 2. DLC and PCB concentrations in maternal blood, and mercury in maternal hair samples

TEQs were calculated using toxic equivalency factor values (Van den Berg et al., 2006). IQR, interquartile range; DLCs, dioxin-like compounds; TEQ, toxic equivalent; PCDD, polychlorinated

dibenzo-p-dioxins; PCDF, polychlorinated-dibenzofuran; PCB, polychlorinated biphenyl.

p-values were calculated using the Mann-Whitney U test.

## 332 *3.2 Oddball task results*

333	Task performance during ERP recordings is shown in Table 3. The omission error rate, which is
334	the rate of failure to press the button for the target stimulus was higher in the difficult condition
335	than in the easy condition, t (54) = 16.93, $p < 0.01$ , $r = 0.92$ . The false alarm rate, defined as the
336	rate of button presses in response to the non-target or standard stimulus, was higher in the difficult
337	condition than in the easy condition, t (54) = 6.03, $p < 0.01$ , $r = 0.63$ . The reaction time to the
338	target stimulus was shorter in the easy condition than in the difficult condition, t (54) = 12.52, p
339	< 0.01, r = 0.86. These behavioral results indicate successful manipulation of the task difficulty.

Table 3 Summary of behavior during oddball task (n = 55)

#### 341 SD, standard deviation

Figure 3 illustrates the grand-averaged ERP waveform from three electrodes (Fz, Cz, Pz) in response to the standard, target, and non-target stimuli. We observed P3a around 400 ms after the

- 344 non-target stimulus presentation in the Cz region in both conditions. P3b was clearly observed
- 345 when the target stimulus was presented from 400 to 600 ms over the Pz region.

359 Figure 3. Grand averaged waveform from all participants in each condition from three electrode

362 Figure 4 summarizes the peak latency and mean amplitude of P3a and P3b under the easy and

- 363 difficult condition. For P3a latency, one-factor ANOVA [2 Difficulty level (easy vs. difficult)]
- 364 revealed no significant difference between conditions, F (1, 54) = 1.75, p = 0.19,  $\eta_p^2 = 0.03$ . For

365	P3a mean amplitude, two-factor ANOVA [2 Difficulty level (easy vs. difficult) × 3 Electrode (Fz,
366	Cz, vs. Pz)] revealed a significant main effect of difficulty, F (1, 54) = 8.63, p = 0.005, $\eta_p^2 = 0.14$ ,
367	and electrode, F (2, 108) = 153.71, p < 0.001, $\epsilon$ = 0.76, $\eta_p^2$ = 0.74. Post hoc comparison for the
368	main effect of electrode showed that P3a amplitudes were significantly different among all
369	electrodes, $p < 0.001$ . These results indicate that P3a latency was not modulated by task difficulty;
370	furthermore, the amplitude was larger in the difficult condition than in the easy condition and had
371	a dominant distribution from the central to the parietal scalp region.
372	With respect to P3b latency, one-factor ANOVA revealed shorter latency in the easy condition
373	than in the difficult condition, F (1, 54) = 1.75, p < 0.001, $\eta_p^2 = 0.52$ . Two-factor ANOVA revealed
374	a significant interaction for P3b amplitude, F (2, 108) =33.00, p < 0.001, $\epsilon$ = 0.66, $\eta_p^2$ = 0.38. Post
375	hoc comparison for the interaction showed significant differences in P3b amplitude between the
376	easy and difficult conditions at Fz and Pz. These results indicate that the amplitude was larger in
377	the easy condition than in the difficult condition at the Pz scalp region and vice-versa in the Fz
378	region.

### 394 *3.3 Association between contaminants, behavioral performance, and P3*

The association between maternal DLC, PCB, or HHg concentration, and behavioral performance during the oddball task is shown in Table 4. There was no significant association between the omission error rate and false alarm rate. Reaction time was significantly and negatively associated with PCDF in the difficult condition ( $\beta = -132$ ; 95% confidence interval [CI]: -251, -14), and HHg in both conditions ( $\beta = -97$ ; 95% CI: -175, -19 for easy, and  $\beta = -99$ ; 400 95% CI: -192, -6 for difficult level, respectively).

### 401 Table 4. Association between behavioral performance and maternal DLC, PCB-153, or HHg concentration (n = 55).

CI, confidence interval; DLC, dioxin-like compound; TEQ, toxic equivalent; PCDD, polychlorinated dibenzo-*p*-dioxins; PCDF, polychlorinateddibenzofuran; PCB, polychlorinated biphenyl; HHg, mercury concentration in hair samples.

Models were adjusted by maternal age, parity, breastfeeding period, and age at examination. The blood sampling period was added to the models for DLC and PCB-153.

The omission error rate indicates the prevalence of missing to press the button to the target stimulus, false alarm rate indicates the prevalence of button press to the standard stimulus. The hit reaction time is the mean f time from stimulus presentation to the button press to the target stimulus \*p < 0.05,  $^{\dagger}p < 0.1$ 

403	Table 5 shows the association between maternal DLC, PCB, or HHg concentration, and P3
404	latency or amplitude. While P3b latency was negatively associated with HHg in the difficult
405	condition ( $\beta$ = -71; 95% CI: -132, -11), no other association was observed regarding P3a and P3b
406	latency. Regarding P3a amplitude, non- <i>ortho</i> PCBs ( $\beta$ = -4.7; 95% CI: -9.2, -0.2), mono- <i>ortho</i>
407	PCBs ( $\beta$ = -6.1; 95% CI: -11.3, -0.8), and HHg ( $\beta$ = -5.5; 95% CI: -10.4, -0.6) had a negative
408	association in the easy condition, and PCDD ( $\beta$ = -8.6; 95% CI: -16.3, -0.9), PCDF ( $\beta$ = -11.3;
409	95% CI: -18.5, -4.0), non- <i>ortho</i> PCBs ( $\beta$ = -7.6; 95% CI: -12.7, -2.5), mono- <i>ortho</i> PCBs ( $\beta$ = -
410	7.4; 95% CI: -13.5, -1.3), total DLC ( $\beta$ = -10.4; 95% CI: -17.8, -3.1), and HHg ( $\beta$ = -7.2; 95% CI:
411	-13.1, -1.3) had a negative association in the difficult condition. Regarding P3b amplitude, mono-
412	<i>ortho</i> PCBs ( $\beta$ = -9.7; 95% CI: -18.5, -0.9) and PCB-153 ( $\beta$ = -9.2; 95% CI: -18.2, -0.2) had a
413	negative association in the easy condition, and PCDD ( $\beta = -11.6$ ; 95% CI: -22.1, -1.1), PCDF ( $\beta$
414	= -16.2; 95% CI: -26.0, -6.3), non- <i>ortho</i> PCBs ( $\beta$ = -10.1; 95% CI: -17.1, -3.1), mono- <i>ortho</i>
415	PCBs ( $\beta = -9.4$ ; 95% CI: -17.8, -1.0), total DLC ( $\beta = -14.4$ ; 95% CI: -24.4, -4.4), and PCB-153
416	$(\beta = -9.0; 95\%$ CI: -17.6, -0.4) had a negative association in the difficult condition.

#### 418 **4. Discussion**

419 In this study, we examined the association between prenatal exposure to DLC, PCB, or MeHg 420 and the cognitive processing of children during a 3-stimulus oddball task using P3a and P3b. 421 Regarding the behavioral performance, there was a negative association between the reaction time 422 to target stimulus and PCDF level in difficult conditions, and MeHg exposure level in both easy 423 and difficult conditions. P3a amplitude decreased with non- and mono-ortho PCB and MeHg 424 levels regardless of task difficulty, and with PCDD, PCDF, and total DLC levels alone in the 425 difficult condition. P3b latency shortened with MeHg in the difficult condition, and P3b amplitude 426 decreased with mono-ortho PCBs and PCB-153 in both conditions, and PCDD, PCDF, non-ortho 427 PCBs, and total DLC in the difficult condition. 428 Regarding the DLC concentration, the median total TEQ level in this study was 17.24 TEQ pg/g 429 lipid, which was lower than that reported by other studies; more specifically, 22.1 TEQ pg/g lipid 430 in Japan (Masuda et al., 2005), 35.8 TEQ pg/lipid in Holland (Weisglas-Kuperus et al., 2000), 431 28.4 TEQ pg/lipid in Germany (Wittsiepe et al., 2007), and 39.1 TEQ pg/lipid in America 432 (Schecter et al., 2005). The PCB concentration in this study is also considered lower than in 433 previous studies. Chen and Hsu (1994) reported that children were accidentally exposed to 434 extremely high PCBs levels. Vreugdenhil et al. (2004) reported that the sum of four PCB 435 congeners (International Union of Pure and Applied Chemistry [IUPAC] numbers 118, 138, 153,

436	and 180) in the high exposure group was 2.54 $\mu$ g/l median; in the present study the median sum
437	of the same four congeners was 0.20 ng/g in whole blood (which is approximately the same as
438	$0.20 \ \mu g/Kg$ ). Boucher et al. (2010) reported that the PCB-153 cord blood level was 103.0 ng/g fat
439	median, higher than the PCB-153 level in the present study (25.6 ng/g lipid as shown in Table 2).
440	With respect to the behavioral performance during the oddball task, there was a negative
441	association between the reaction time to target stimulus and PCDF level in difficult conditions,
442	and MeHg exposure level in both easy and difficult conditions. In other words, the reaction time
443	became shorter with increasing exposure to MeHg. Furthermore, P3b latency, which reflects
444	response decision and correlate with reaction time, was also shortened in association with MeHg
445	levels under the difficult condition. The results are counterintuitive because shorter reaction time
446	or rapid decision making reflected by P3 latency are generally favorable. This might be due to
447	nutritional factors such as fatty acids, which have beneficial effects on brain development (Choi
448	et al, 2014, Saint-Amour et al., 2006). On the other hand, P3a and P3b amplitudes were
449	significantly associated with various exposures. Boucher (2010) also found a significant
450	association of PCB exposure with P3b amplitude for breast feeding < 3months, but not with
451	behavioral performance. Taken together, it might indicate higher ERP sensitivity for specific
452	aspects of cognitive processes, as attentional resources etc., which are difficult to detect in
453	behavioral performance.

454	Regarding the association between DLC and P3b during the oddball task, Schellart & Reits
455	(2008) reported that the latencies increased and that the amplitudes decreased in response to the
456	oddball task in the higher exposure group to dioxin, but not to P3a (their P3a data were not shown).
457	Although it is difficult to compare the results directly because they calculated the latencies and
458	amplitude using original methods, a decrease in amplitude as a response to oddball task in the
459	higher dioxin level group seems consistent with the present results. However, we observed an
460	association between DLC levels and P3a amplitude. This may be due to the 3-stimulus oddball
461	task with two difficulty levels in our study, which elicited larger P3a waves, and enabled the
462	detection of the association between P3a and DLC.
463	With consideration to PCB, we found an association between the increase in PCB-153 and the
464	decrease in P3b amplitude, both in the easy and difficult conditions. Chen and Hsu (1994) reported
465	an increase in P3b latency and decrease in amplitude, and Vreugdenhil et al. (2004) reported an
466	increase in P3b latency without amplitude modulation in the PCB higher exposure group.
467	However, Boucher et al. (2010) found an association between PCB exposure and a decrease in
468	P3b amplitude only in a subgroup of children who had been breastfed for $< 3$ months; no
469	association was found regarding latency. The exposure levels of PCBs are reportedly higher in
470	the abovementioned studies than in the present study results; the concentration level does not
471	sufficiently explain the inconsistency of the results. The inconsistency may be due to differences

472 in the study design, the type of oddball task, and sensory modalities.

473	Interestingly, we found different patterns of association between P3a or P3b amplitudes and HHg
474	and PCB-153 levels. Nieuwenhuis et al. (2005) suggested that P3a and P3b reflect the response
475	of the locus coeruleus-norepinephrine system, and that one region surrounding the
476	temporoparietal region (TPJ) was critical for the generation of both the P3a and the P3b. Another
477	region, in the lateral prefrontal cortex, is critically involved in the generation of the P3a by novel
478	stimuli. The fact that the amplitude of P3a decreased as the HHg levels increased, but P3b did not
479	change indicates that MeHg might tap the attentional capture process reflected by P3a (Escera et
480	al., 1998; Friedman et al., 2001; Rushby et al., 2005; Sawaki & Katayama, 2008) and the source
481	of P3a located at lateral prefrontal cortex (Nieuwenhuis et al., 2005). On the other hand, only P3b
482	amplitude was negatively associated with the PCB-153 level. PCB exposure might be associated
483	with voluntary attentional allocation and evaluation reflected by P3b (e.g., (Donchin, 1981;
484	Katayama & Polich, 1996a; Sutton et al., 1965).
485	The present results that both P3a and P3b amplitudes are associated with DLC levels might be
486	explained by the fact that excitatory postsynaptic potentials (EPSPs), a cause of scalp-recorded
487	P3a and P3b (Frodl-Bauch et al., 1999), could be altered by DLC exposure directly in an animal
488	experiment (Hong et al., 1998). Additionally, the glutamatergic metabolic system might be a
489	MeHg exposure mechanism because the glutamine/glutamate ratio in the anterior cingulate cortex

490	has a positive correlation with P3a amplitudes but not with P3b amplitude (Hall et al., 2015), as
491	shown in the present study. It is difficult to interpret the association between PCB and P3b
492	amplitude because P3b is influenced by multiple sources (Nieuwenhuis et al. 2005). One possible
493	mechanism is the influence of thyroid hormones, which act on the migration and differentiation
494	of nerve cells, synapse formation, and myelination in various parts of the brain during pregnancy
495	and the early postnatal period (Bernal, 2007). Although a previous study reported the absence of
496	an association between maternal PCB levels and maternal and neonatal thyroid hormones (Baba
497	et al., 2018), another suggested that hydroxylated PCBs, the predominant metabolites of PCBs,
498	had effects on fetal thyroid functions (Itoh et al., 2018). From a different perspective, one might
499	consider that these associations come from children's fatigue and motivation, not from alterations
500	of the cognitive process itself. However, we did not observe a negative association between
501	exposure and behavioral results, which is thought to be related to these factors. Additionally,
502	different cognitive processes reflected by P3a and P3b show different modulations. Therefore, the
503	children's fatigue and motivation could not explain these present results.
504	A major strength of our study was that the outcome of cognitive function in children was
505	measured by ERP without examiner bias, which is often problematic with psychological testing.
506	Additionally, we adopted a 3-stimulus oddball paradigm with two difficulty levels, which enabled
507	the discrimination between P3a and P3b and the individual cognitive processes they reflect.

508 Although previous studies have analyzed either PCBs or dioxins (Chen & Hsu, Vreugdenhil 2004, 509 Shellart 2008), or PCBs and MeHg (Boucher 2010), we found different patterns of association 510 between P3a/b and DLC, PCB, or HHg by analyzing these compounds. 511 One limitation of our study was that only a small number of participants agreed to participate in 512 the ERP experiment. In addition, the data was limited in the ERP analysis where noisy data had 513 to be excluded (n=55). According to Cohen's guidelines, our analysis could detect a medium to 514 large effect size but might miss small associations. Additionally, the comparison of baseline 515 characteristics showed older maternal age, higher educational levels, and lower smoking 516 prevalence in participants in the study, in whom DLC or PCB concentration was also higher than 517 in non-participants. These differences mean that participants in the present study might conform 518 a slightly biased population. To generalize the results of this study, a bigger sample should be 519 analyzed. Another limitation is the long time-window from prenatal exposure to the ERP outcome 520 in school age. Although Chu et al. (2019) demonstrated using structural and functional magnetic 521 resonance imaging (MRI) that prenatal exposure to a high level of PCBs was associated with 522 brain structure and function in men aged approximately 30 years, the limitation remains that we 523 could not analyze postnatal exposure to DLC, PCB, and MeHg and other chemicals. It is primarily

525 dietary sources of these chemicals and might include other common toxicants. Although the

524

needed to examine multiple exposures because fish and seafood consumption would be the main

526	association between P3a/b and exposures seems consistent, these results should be carefully
527	considered because of the multiple regression analyses. Despite these limitations, the results of
528	the analysis showed an association between fetal exposure to the studied substances and P3, which
529	is considered a valuable finding in line with previous studies. Further research is needed to
530	investigate the relevant mechanisms observed in the current study and whether they continue until
531	adulthood.
532	
533	5. Conclusions
534	The reaction time to the target stimulus during oddball task became shorter as the exposure level
535	to MeHg increased. Furthermore, P3b latency, which reflects response decision and correlates
536	with reaction time, was also shortened in association with MeHg levels under the difficult
537	condition. It might be due to nutritional factors such as fatty acids, which have beneficial effects
538	on brain development. An association between prenatal exposure to DLC and a decrease in both
539	P3a and P3b amplitudes was found, even when DLC levels were lower than reported in most
540	previous studies. Additionally, our results suggest that the automated attention capture process
541	reflected by P3a was associated with maternal HHg, and the voluntary attention allocation process
542	reflected by P3b was associated with PCB-153 in maternal blood. However, these results should
543	be considered carefully because of the limitations on sample size, population bias, and statistical

544	analyses.
