1    **Abstract**

2                    Krabbe disease is a lysosomal storage disease caused by a deficiency of the  
3    galactocerebrosidase (GALC) enzyme, which leads to demyelination of the central and  
4    peripheral nervous systems. Almost all patients with Krabbe disease are infants, and this is the  
5    first report of adult-onset cases that describe pathological findings. Here, we present two  
6    autopsy cases: a 73-year-old female and a 2-year-old male. The adult-onset case developed  
7    symptoms in her late thirties and was diagnosed by the identification of GALC D528N and  
8    L634S mutations and by T2-weighted magnetic resonance imaging; she had increased signal in  
9    the white matter along the pyramidal tract to the bilateral precentral gyrus, as well as from the  
10   triangular part to the posterior horn of the lateral ventricle. Microscopically, Klüver–Barrera  
11   staining was pale in the white matter of the precentral gyrus and occipito-thalamic radiation, and  
12   a few globoid cells were observed. The *GALC* mutations that were identified in the present  
13   adult-onset case do not completely inactivate GALC enzyme activity, resulting in focal  
14   demyelination of the brain.

18

19 **Introduction**

20 Krabbe disease (globoid cell leukodystrophy), which was identified by Krabbe in 1916 <sup>1</sup>,  
21 is an autosomal recessive leukodystrophy with a morbidity of one in two hundred thousand  
22 people. It is classified as a lysosomal storage disease and is caused by deficiency of the  
23 galactocerebrosidase (GALC) enzyme, which leads to demyelination of the central and  
24 peripheral nervous systems <sup>2,3</sup>. Most cases (95%) of Krabbe disease are infantile onset (before  
25 the age of 6 months) <sup>4</sup>. Clinical manifestations of the disease include hyperirritability,  
26 hypersensitivity, stiffness, episodic fever, hypertonicity, decerebrate posturing, blindness, and  
27 unresponsiveness. Most patients die by the age of 2 years. Three other onset types of the disease  
28 are recognized: late infantile (6 months to 3 years), juvenile (3 to 8 years), and adult (after 20  
29 years). The manifestations of adult-onset disease include asymmetric limb weakness, spastic  
30 gait, poor coordination for balance, and tremors; the symptoms mimic those of motor neuron  
31 disease <sup>5,6</sup>. The disease progresses slowly in some patients, who have a normal life span. This  
32 report compares an adult-onset case with an infantile-onset case using both autopsy and  
33 pathological findings.

34

35 **CASE 1**

36 **CLINICAL SUMMARY**

37                   This was a female autopsy case that was 73 years old. The patient noticed  
38 difficulties with lifting her legs in her late thirties. From 56 to 62 years of age, she used crutches  
39 to walk and then progressed to a wheelchair. Neurological manifestations at the age of 67  
40 included amyotrophy of the distal muscles in the bilateral limbs (manual muscle test: proximal  
41 muscles 2–3, distal muscles 1–2), walking difficulties, jaw jerk reflex, periosteal reflex of the  
42 limbs, Babinski reflex were positive, sensation disorder beyond both knees, and axonopathy of  
43 the limbs (in a nerve conduction test). On magnetic resonance imaging (MRI; T2-weighted), the  
44 cerebral white matter showed increased signals (1) along the pyramidal tract to the bilateral  
45 precentral gyrus and (2) from the triangular part to the posterior horn near the lateral ventricle  
46 (especially the occipito-thalamic radiation) (Fig. 1A). These findings were unchanged for 13  
47 years until her death. The patient was diagnosed with Krabbe disease because of MRI findings  
48 and the identification of GALC mutations (D528N and L634S mutations) when she was 71  
49 years old. She died of aspiration pneumonia aged 73.

50

#### 51 PATHOLOGICAL FINDINGS

52                   Macroscopically, a white matter lesion around the central sulcus was not obvious  
53 (Fig. 1B). Microscopically, the white matter of the precentral gyrus was pale using Klüver–  
54 Barrera (KB) staining (Fig. 1C). In this area, mild astrocytosis and a few multinucleated giant

55 cells with scant cytoplasm and oval nuclei were identified (Fig. 1D). These multinucleated cells  
56 were positive for Periodic acid–Schiff (PAS) stain (Fig. 1E) and CD68 (Supplementary Fig. 1B),  
57 and were consistent with globoid cells: the characteristic macrophages of Krabbe disease. There  
58 were few T-cells around the vessels. The white matter was strongly positive for neurofilament  
59 staining without spheroids; therefore, demyelination is mild (Supplementary Fig. 3A–C). The  
60 pyramidal tracts of the midbrain and cervical spinal cord were degenerated and exhibited slight  
61 myelin pallor (Supplementary Fig. 1C).

62

## 63 **CASE 2**

### 64 **CLINICAL SUMMARY**

65 This was a male autopsy case that was 1 year and 7 months old. The patient had notably  
66 delayed milestones of physical development at the ages of 3 and 6 months. At the age of 9  
67 months, enlargement of the subarachnoid space was apparent in computed tomography, early  
68 closure of the coronal suture was observed by skull X-ray, and delayed myelination was seen on  
69 MRI. Furthermore, his cerebrospinal fluid protein was elevated (110 mg/dL). At the age of 11  
70 months, he lost eye contact and head control, and brain atrophy and demyelination were noted  
71 on MRI (Fig. 2A). At 1 year and 4 months of age, truncal opisthotonus and rigid–spastic  
72 extremities were noted. Massive myoclonus and brief tonic seizures also appeared. At the age of

73 1 year and 6 months, he had respiratory failure and apparent weight loss. At 1 year and 7  
74 months of age, he was hospitalized with bacterial pneumonia and died of severe respiratory  
75 failure. His lysosomal enzyme activity test revealed that he had low GALC activity (Table 1).

76

## 77 PATHOLOGICAL FINDINGS

78 Macroscopically, white matter lesions around the internal capsule and cerebral ventricle  
79 was noted as light brown and transparent (Fig. 2B). The white matter of the cerebrum and  
80 cerebellum was pale in KB staining, but was stained well with Holzer staining, thus suggesting  
81 fibrillary gliosis (Fig. 2C). White matter was severely disrupted, and foamy macrophages,  
82 globoid cells, and marked astrocytosis were observed. Countless globoid cells had abundant  
83 cytoplasm, oval nuclei (Fig. 2D), and PAS-positive inclusions (Fig. 2E). Gliosis was severe  
84 with numerous fibrillary astrocytes and gemistocytes (Supplementary Fig. 2B). There was some  
85 T-cell infiltration around the vessels. Marked demyelination was observed with no remaining  
86 axons in neurofilament staining, but only U-fibers between the gray and the white matter were  
87 stained well (Supplementary Fig. 3D–F).

88

## 89 Discussion

90 Compared with the infantile-onset case, the adult-onset case progressed gradually, and the

91 symptoms were more focused. A table showing the comparisons between the two cases is  
92 included (Table 1). The adult-onset case showed a mild disorder of movement, sensation, neural  
93 reflex, amyotrophy, and axonopathy in all four limbs (especially in the inferior limbs). In  
94 contrast, the infantile-onset case showed rapid development throughout the whole body and  
95 involved a developmental delay of psychomotor performance. In both cases, the activity of  
96 GALC was unable to be detected by laboratory tests. Microscopically, the convolutional white  
97 matter of the precentral gyrus and occipito-thalamic radiation was demyelinated in the  
98 adult-onset case, while all white matter—in both the cerebrum and cerebellum—was affected in  
99 the infantile-onset case (Fig. 3). Degeneration of the pyramidal tract throughout the midbrain to  
100 the spinal cord was observed in both cases. Additionally, only a few globoid cells with scant  
101 cytoplasm and oval nuclei were observed in the adult-onset case; in contrast, these cells were  
102 present in large quantities with abundant cytoplasm, oval nuclei, and PAS-positive inclusions in  
103 the infantile-onset case. Gliosis and demyelination were mild, and axons remained in the  
104 adult-onset case, whereas severe gliosis and demyelination lead to marked axonal degeneration  
105 in the infantile-onset case.

106           In adult-onset cases, demyelination is generally localized in the precentral gyrus and  
107 occipito-thalamic radiation. GALC, which is deficient in Krabbe disease, dissolves important  
108 components of myelinization in cells, such as galactosylceramide and psychosine <sup>7</sup>. An

109 accumulation of these substances causes cell damage and leads to the appearance of globoid  
110 cells and demyelination. Thus, frequent myelin turnover can be the main lesion of  
111 demyelination<sup>8</sup>. The white matter of the precentral gyrus, which was damaged in the present  
112 adult-onset case, has neural fibers of the corticospinal tract that travel from Betz cells in the  
113 precentral cortex to the lumbo-sacral cord. These are one of the longest and largest neural fibers  
114 in the human body<sup>9</sup>, and their myelin turnover may be more active than the others. The  
115 precentral gyrus might therefore be prone to accumulating substances such as  
116 galactosylceramide and psychosine, and thus be more vulnerable to demyelination. White  
117 matter lesions of the triangular part of the posterior horn involve a pathway that is related to  
118 vision: the occipito-thalamic radiation. Our adult-onset case showed a focal lesion with a few  
119 globoid cells in this area, which might have been caused by unknown characteristics of myelin  
120 structure or by oligodendrocytes in the occipito-thalamic radiation.

121 Krabbe disease is caused by mutations in the *GALC* gene that result in degeneration of  
122 the GALC protein. GALC consists of 668 amino acids and has three representative domains (the  
123 triose-phosphate isomerase [TIM] barrel,  $\beta$ -sandwich domain, and lectin domain)<sup>10</sup>. These  
124 domains combine to form a large substrate-binding pocket. Fig. 4 shows the typical mutation  
125 sites in the GALC protein that have been found in adult- or infantile-onset patients with Krabbe  
126 disease. The mutation sites vary widely but appear to be concentrated in the TIM barrel and

127 lectin domains. Typical examples of mutations in adult-onset cases include L634S,  
128 [I82M+I305V], and G286D<sup>11</sup>, while c.683\_694delinsCTC (N228\_S232delinsTP), T668P,  
129 R220X, 30kDa del, and D528N are more common in infantile-onset cases<sup>11</sup>. In our adult-onset  
130 case, L634S and D528N were identified. The L634S substitution occurs in the lectin-binding  
131 domain, and has been demonstrated to impair the transport of GALC to lysosomes<sup>12</sup>.  
132 Furthermore, the D528N substitution does not result in a complete loss of enzymatic activity in  
133 GALC, but its transport into the lysosome is impaired, resulting in a decrease in enzymatic  
134 activity<sup>13</sup>. The identified mutations in the present case, L634S and D528N, are characteristic of  
135 adult- and infantile-onset cases, respectively; however, the combination of these mutations  
136 seems to have resulted in the adult-onset form of the disease. Neither mutation completely  
137 inactivates GALC, but they impair its transport to lysosomes, which results in a relatively mild  
138 phenotype. Thus, the combination of mutation sites may also be important in determining the  
139 type of disease.

140 In the present report, the adult-onset case exhibited a milder clinical course than the  
141 infantile-onset case. Additionally, the demyelinated lesions were limited to the precentral gyrus  
142 and triangular area of the posterior horn, and were accompanied by just a few globoid cells. The  
143 GALC mutations L634S and D528N do not completely inactivate GALC enzyme activity, thus  
144 resulting in focal demyelination of the brain.

## Figure legends

### Fig. 1 Radiological and pathological images of the adult-onset case (Case 1).

(A) Magnetic resonance images (T2-weighted images) 13 years before death showing high intensity in the white matter from the triangular part to the posterior horn in the lateral ventricle (arrows) and along the pyramidal tract to the bilateral precentral gyrus (arrowheads); these findings do not change until death. (B) No remarkable findings around the central sulcus (left) and posterior horn (right) in a coronal section macroscopically. (C) The white matter of the precentral gyrus showing myelin pallor in Klüver–Barrera staining. (D) A few globoid cells with scant cytoplasm and oval nuclei, and mild astrocytosis in the demyelinated lesions. (E) Globoid cell positive for Periodic acid–Schiff staining. Scale bars: 50 mm (B), 10 mm (C), 5  $\mu$ m (D, E).

### Fig. 2 Radiological and pathological images of the infantile-onset case (Case 2).

(A) Magnetic resonance images (T2-weighted images) at the age of 11 months (8 months before death) showing high intensity in the posterior horn of the lateral ventricle (arrows). (B) The white matter around the internal capsule and cerebral ventricle showing brownish and transparent, macroscopically. (C) The white matter around the cerebral ventricle showing myelin pallor in Klüver–Barrera staining and fibrillary gliosis by Holzer staining. (D) Countless globoid cells with abundant cytoplasm and oval nuclei, and marked gliosis. (E) Globoid cell inclusions positive for Periodic acid–Schiff staining.

Scale bars: 50 mm (B, C), 5  $\mu$ m (D, E).

### Fig. 3 Distribution of the lesions.

The demyelinated lesion is colored red, and the secondary degeneration is depicted in blue. The main lesion is localized in the adult-onset case (Case 1) and is widespread in the infantile-onset case (Case 2). Both cases exhibit secondary degeneration of the pyramidal tract.

### Fig. 4 Locations of amino acid substitutions in *GALC*.

The specific mutations for adult-onset disease, such as L634S (our case has this mutation) and G286D,

are colored red. In contrast, mutations in blue are common in infantile-onset disease (e.g., c.683\_694delinsCTC and T668S).

## Tables

**Table 1** Summary of the adult-onset case (Case 1) and the infantile-onset case (Case 2)

	<b>Case 1</b>	<b>Case 2</b>
<b>Age of onset</b>	Mid-30s	3 months
<b>Symptoms</b>	Limb weakness Walking difficulty Spastic gait Amyotrophy of distal muscle, especially bilateral limbs Jaw jerk reflex, limbs periosteal reflex, Babinski's reflex All sensation disorder beyond both knees Axonopathy of limbs	Psychomotor retardation Dilation of circumference and subarachnoid cavity Delay of myelination Cerebrospinal fluid protein abnormality Delay of peripheral nerve conduction velocity Opisthotonos of trunk Rigidity and spasm Massive myoclonus Tonic seizure Respiratory disorder
<b>Disease progression</b>	Slow	Rapid
<b>Galactocerebrosidase</b> Reference value $0.75 \pm 0.27$ (mol/h/mg)	0.08	Trace
<b><i>GALC</i> mutation</b>	D528N, L634S	Not examined
<b>Lesions</b>	White matter close to precentral gyrus and posterior horn of lateral ventricle (localized) Secondary degeneration of the pyramidal tract	Cerebrum and cerebellar white matter (extensive) Secondary degeneration of the pyramidal tract
<b>Globoid cell</b>	A few (one cell in one slide)	Countless
<b>Number</b>	Scant	Abundant
<b>Cytoplasm</b>	Oval	Oval
