# Technical details in statistical estimation

# S1.1 Logistic regression model for estimating clonal growth $C_j^h$

In order to estimate  $C_j^{1-y-\text{tip}}$  and  $C_j^{2-y-\text{tip}}$ , pooling the four growing seasons (2006 summer to 2009 summer), the logistic regression model was applied in which covariates were age-positions and sizes classes and the objective variable was the presence/absence of clonal growth:

 $y = 1/\{1 + \exp(a^{1}x^{1} + a^{2}x^{2} + a_{1}x_{1} + \dots + a_{5}x_{5})\}$ 

where  $x^1$  and  $x^2$  were dummy variables of age-position (1-y-tip and 2-y-tip, respectively),  $x_1, ..., x_5$  were those for the five size classes, and  $a^1, a^2, a_1, ..., a_5$  were free parameters;  $a^1$ : 1-y-tip,  $a^2$ : 2-y-tip,  $a_1$ : 1L,  $a_2$ : 2L-<10,  $a_3$ : 2L-10–15,  $a_4$ : 2L-15–20,  $a_5$ : 2L- $\geq$ 20. Because one was redundant,  $a^1$  was fixed at 0.  $C_j^h$  is given by, for example,  $C_{1L}^{1-y-tip} = 1/\{1 + \exp(a^2 + a_2)\}, C_{2L-10-15}^{2-y-tip} = 1/\{1 + \exp(a^2 + a_2)\}$ , and so on.

# S1.2 Clonal growth $C_j^h$ when some information was missing

When size information was missing, depending on missing patterns, we used the following dummy variables for the size classes.

If we had no size information in year t but had in year t - 1 (size class k), we used the dummy variable as  $x_i = T_{ik}$ .

If there was no size information in year t and t - 1 but had in year t - 2 (size class k), we used the dummy variable as  $x_j = (\mathbf{T}^2)_{jk}$ .

If there was no size information in year t but had in year t + 1 (size class i), we used the dummy variable as  $x_j = T_{ij}/\sum_l T_{lj}$ , i.e., the conditional probability given size class *i* in the subsequent year.

If there was no size information in year t but had in year t - 1 (size class k) and t + 1 (size class i), we used the dummy variable as  $x_j = T_{ij} T_{jk} / \sum_l T_{ll} T_{lk}$ .

These modifications were for the following cases. Some ramets were not present in a census (year t) but observed in the previous and the subsequent years (year t - 1and/or t + 1). This happened probably when an aboveground shoot emerged after the census in year t, or that ramet did not produce a shoot. Because we stopped the annual census in 2007, there was no plant size information in 2008 and 2009.

# S1.3 Clonal reproduction $C_j^h$ when birth year was not identifiable

When the birth year was unknown (either 2008 or 2009), for simplicity, the same probability (0.5) was given to the two cases. This happened for new ramets in 2009.

#### S1.4 Excluded cases from statistical analysis

We found isolated ramets (no rhizome was connected) and almost isolated ones (only interrupted rhizome(s) was connected). There are two possibilities; (1) at the tip and the rhizome from the mother was disappeared, (2) at the non-tip and all the rhizomes were disappeared. Because we did not have any evidence to distinguish the two, these were excluded from the logistic regression. In addition, we found new 14 buds on fragments that had no living shoot (only with interrupted rhizome or a dead ramet). These were not used in the logistic regression (S1.1), either.

Note: The clonal growth frequency of the isolated ramets was 3.2% (5 over 154, genets and size classes were pooled), which was smaller than that of almost isolated ramets (7.0%, 10 over 142), and these were smaller than that of 2-y-tip (Fig. S2 in Appendix III), but higher than branching (Table S2b). These might suggest the capability of clonal growth for a long period with slowly decreasing rates for *C. keiskei*.

#### S1.5 Bayesian estimation

In order to evaluate sampling bias caused by small sample size, Bayesian statistics was applied. For the distribution of newly born ramets (**N**) and the elements in each column of the transition matrix (**T**), the multi-nominal distribution and the flat conjugate Dirichlet prior were applied. For the branching probabilities ( $C^{\text{non-tip}}$ ) and the survival (**S**), we applied the binomial distribution and the flat conjugate Beta prior.2,000 random samples were produced from each posterior distribution (Table S2c for **N**, Table S2b for  $C^{\text{non-tip}}$ ) and Table S2d for **S**, Table S2e for **T**).

For the coefficients of the logistic regression of the clonal growth (the equation in S1.1), we used flat priors of wide range (-10, 10) with constrain  $a_2 \le a_3 \le a_4$ ,  $a_3 \le a_5$ , which means that for ramets with two leaves (2L), larger ramets tended to reproduce more frequently and the largest two classes  $(a_4, a_5)$  may have similar probabilities.

The Markov chain Monte Carlo (MCMC) of the Metropolis-Hastings algorithm updated by random walk was conducted with initial values at 0. From the total 65,000 MCMC iterations, the first 5,000 iterations were discarded as a burn-in period, and every 30 was chosen to produce 2,000 MCMC samples (Table S2a). 2,000 random samples of  $C_j^h$  were produced by transforming them as  $C_{1L}^{1-y-\text{tip}} = 1/\{1 + \exp(a_2)\}, C_{2L-10-15}^{2-y-\text{tip}} = 1/\{1 + \exp(a^2 + a_2)\}$ , and so on (Fig. S2).
