1. A local shear strength method is proposed for evaluating the variation of the shear strength for each soil material point.
2. A FEM-MPM hybrid coupled framework is proposed to simulate rainfall/runoff triggered landslide runout in unsaturated slopes.
3. Simultaneous analysis of runoff, seepage, and landslide runout within a small catchment scale is successfully performed.

31 **Abstract**

32 Limited by the independence and its defects of each general software package, simultaneous analysis  
33 of runoff, seepage, and large-deformation analysis is still an inevitable challenge. Generally, one of  
34 seepage, landslide-related large-deformation, and runoff is ignored or indirectly assessed during  
35 unsaturated soil landslide runout simulation. To provide a brand new solution, this paper declares a  
36 local shear strength (LSS) method to evaluate rainfall/runoff-induced reduction of the unsaturated soil  
37 shear strength. After that, a hybrid coupled hydro-mechanical framework is proposed to simulate  
38 rainfall/runoff-induced landslide runout within an unsaturated soil slope. The decrease in local shear  
39 strength corresponding to the decrease in matric suction is defined by shifting the Mohr-Coulomb  
40 (M-C) failure envelope towards compressive stress space during rainfall/runoff infiltration. Based on  
41 the proposed local shear strength method, the variable matric suction obtained from the bidirectionally  
42 coupled runoff and seepage analysis in FEM is unidirectionally transferred to the variable local shear  
43 strength for each soil material point in MPM (i.e., this is a FEM-MPM hybrid coupled model). Then,  
44 the correctness of the proposed hybrid coupled hydro-mechanical framework is effectively verified by  
45 a hypothetical homogeneous slope model. The results show that the slope stable/unstable state  
46 simulated by the proposed hybrid coupled hydro-mechanical framework has a good consistency with  
47 that simulated by the shear strength reduction technique (SSRT) and limit-equilibrium method (LEM).  
48 Afterward, combined with a case study of a natural landslide in Hokkaido, Japan, it is proved to be  
49 effective for simulating landslide runout subjected to rainfall/runoff infiltration by using the proposed  
50 hybrid coupled hydro-mechanical framework in an unsaturated soil slope.

52 runoff; Finite element method; Unsaturated soil slope

53

## 54 **1. Introduction**

55 In many mountainous regions, rainfall/runoff is considered to be the main cause triggering  
56 landslides/slope failures. With the intensification of global and regional climate change, extreme  
57 rainfall events and huge flooding have occurred frequently in recent years (Paerl et al., 2020; Wei et  
58 al., 2020). The decrease in matric suction in the unsaturated zone caused by rainwater infiltration  
59 under torrential rain is considered the main cause of the landslide/slope failure initiation (Zhu et al.,  
60 2020). After the landslide/slope failure occurs, the collapsed soil moves downward, namely landslide  
61 runoff, threatening the lives and properties of residents living downslope, especially those living near  
62 the foothills. Therefore, it is of great social and economic value to study the landslide runoff distance,  
63 reasonably install the disaster prevention measures, and set the evacuation area. Many scholars have  
64 made great efforts to develop numerical methods for simulating landslide runoff, e.g. Discrete  
65 Element Method (DEM) (An et al., 2021), Discontinuous Deformation Analysis (DDA) (Shi, 1989;  
66 Peng et al., 2020), and Material Point Method (MPM) concurrently researched and operated by  
67 several groups (Müller and Vargas, 2019; Acosta et al., 2021; Sun et al., 2021; Ying et al., 2021).  
68 Among them, DEM and DDA consider the geo-material as discrete blocks connected by spring units.  
69 Though DEM and DDA are recognized as having the advantages to simulate the cracking behaviors  
70 of continuous media or model the contact, collision, slipping, and movement of discretely stacked  
71 materials, these two methods also suffer from low convergence, low accuracy, high calibration

72 requirements, and high computational costs. Besides, runoff and seepage analysis are still considered  
73 as the main limitations of them. Furthermore, a depth-integrated continuum method that uses  
74 continuum to model landslide mobility is recently developed by Iverson et al. (2015), Ouyang et al.  
75 (2017), and Ouyang et al. (2019). In this method, integrated by the Navier-Stokes equations and flow  
76 depth, the mass and momentum equations are solved by using the finite difference method. Apart  
77 from these, another method, MPM, is also getting continued attention since it was first formulated by  
78 Sulsky et al. (1994), as it avoids the problem of mesh distortion problems in the FEM and shows  
79 higher computing efficiency compared with DEM and DDA. In MPM, the material bodies are  
80 represented by a large number of material points. The physical information (velocity, acceleration,  
81 mass, etc.) is stored in those material points. During the computational process of MPM, the physical  
82 information will be repeatedly converted between the background grid and the material points to form  
83 a link between the physical information and the spatial position.

84 The single-phase (solid phase) MPM has been maturely adopted to simulate landslides without  
85 considering hydrology. For example, Sun et al. (2015) validated the applicability of the MPM in  
86 simulating runout according to the comparative results of experiments and simulations of a simple  
87 landslide example. Woo and Rodrigo (2018) presented a generalized interpolation MPM to get higher  
88 computational accuracy and efficiency of MPM. Recently, MPM has also been developed to capture  
89 the rapid landslide behavior in the form of a soil-water mixture. The porous solid phase, pore water  
90 phase, and/or pore air phase are characterized by using two or more Lagrangian layers, i.e., two-phase  
91 MPM or multi-phase MPM (e.g., Soga et al., 2016; Liang et al., 2020; Lei et al., 2021). However, it is  
92 worth noting that the objects of the above researches are mainly rainfall-induced landslides/slope

93 failures in saturated soil or unsaturated soil. The runoff analysis with changes in water depth is  
94 neglected since it is considered as one of the fundamental challenges when using either single-phase  
95 and two-phase MPM or multi-phase MPM. From the view of the coupling process of runoff and  
96 seepage, and the variation of matric suction in unsaturated soil, the traditional numerical method,  
97 FEM, has more advantages than other methods. Further, it has been widely used in general  
98 commercial software packages, which are designed to analyze runoff and seepage. For example,  
99 COMSOL Multiphysics (COMSOL Multiphysics, 2018) and GEO-SEEP/W (GeoStudio International,  
100 2007). Therefore, proposing a FEM-MPM coupled computational framework will give full play to  
101 their respective advantages in the coupled simulation of runoff, seepage, and landslide runout.

102         Consequently, the objective of this study was to establish a coupled hydro-mechanical framework  
103 to simulate landslide runout triggered by rainfall/runoff infiltration within an unsaturated slope. To  
104 achieve this goal, this study firstly proposes a local shear strength method for defining the variation of  
105 the local shear strength induced by the rainfall/runoff infiltration for each soil material point. Then,  
106 based on the proposed local shear strength method, a hybrid coupled hydro-mechanical framework is  
107 developed. In the hybrid coupled hydro-mechanical framework, the seepage behavior is captured by  
108 bidirectionally coupled runoff and seepage analysis with the FEM. Then, the variable matric suction  
109 obtained from FEM is unidirectionally transferred to the variable local shear strength of each soil  
110 material point in MPM by using the local shear strength method. The resulting slope failure behavior  
111 is analyzed by the MPM. Thus, a FEM-MPM hybrid coupled model is established. Finally, through a  
112 validation model and a case study of a natural slope, the results proved that the proposed FEM-MPM

113 hybrid coupled model is effective for coupled simulating runoff, seepage, and large-deformation  
114 problems, such as rainfall/runoff-induced landslide runout within an unsaturated slope.

## 115 **2. Definition of local shear strength for each unsaturated soil material point**

116 The saturated soil shear strength for each material point is defined by the Mohr-Coulomb (M-C)  
117 failure criterion,

$$118 \quad \tau_f = c' + \sigma' \tan \phi' \quad (1)$$

119 where,  $\tau_f$  is the shear strength (kPa);  $c'$  is the effective cohesion (kPa);  $\phi'$  is the effective internal  
120 friction angle ( $^\circ$ );  $\sigma'$  is the effective normal stress on failure plane (kPa).

121 In reality, the soil above the phreatic surface is in an unsaturated state. In this state, the soil will  
122 have higher shear strength than in a saturated state. Currently, the well-known method is to describe  
123 the unsaturated soil behavior by using Bishop's effective stress concept (Bishop, 1959),

$$124 \quad \sigma' = (\sigma - u_a)_f + \chi(u_a - u_w)_f, \quad \chi = \frac{S_e - S_r}{1 - S_r} \quad (2)$$

125 where,  $u_a$  is pore air pressure (kPa),  $u_w$  is pore water pressure (kPa);  $\sigma$  is total normal stress (kPa);  $\chi$  is  
126 effective stress parameter;  $S_e$  is effective degree of saturation;  $S_r$  is residual degree of saturation.

127 The unsaturated soil shear strength is also defined by Fredlund et al. (1978),

$$128 \quad \tau_f = c' + (\sigma - u_a)_f \tan \phi' + (u_a - u_w)_f \tan \phi^b \quad (3)$$

129 where,  $\phi^b$  is the angle indicating the rate of increase in shear strength relative to the matric suction  
130  $(u_a - u_w)_f$ .

131 Eqs. (2) and (3) present proper compliance with in-door test results and have been widely used  
132 (Vanapalli et al., 1996). Vanapalli et al. (1996) discussed the applicability of the above two shear  
133 strength models in geotechnical engineering practice and built the relationship between the two

134 models,

$$135 \quad \chi = \frac{\tan \phi^b}{\tan \phi'} \quad (4)$$

136 Therefore, the unified equation form can be written as,

$$137 \quad \tau_f = c' + (\sigma - u_a)_f \tan \phi' + (u_a - u_w)_f \chi \tan \phi' \quad (5)$$

138 which also can be written as,

$$139 \quad \tau_f = \underbrace{[c' + (u_a - u_w)_f \chi \tan \phi']}_{c'_f} + (\sigma - u_a)_f \tan \phi' \quad (6)$$

140 where,  $c'_f$  is the intercept at a specific matric suction,  $(u_a - u_w)_f$ , (kPa).

141 Conventionally, the M-C failure envelope is fixed for the entire slope during rainfall infiltration.

142 Changes in pore water pressure caused by rainfall/runoff infiltration only affect the scaling and

143 translation of the stress circle. Meanwhile, at present, describing the difference in matric suction

144 induced by runoff of various material points is still a potential challenge of the MPM. Therefore,

145 according to Eq. (6), the variation of local shear strength for each material point in MPM can be

146 described by including matric suction in the cohesion intercept. The new cohesion intercept,  $c'_f$ , is

147 called the total cohesion intercept. This provides a feasible way to define the variation of matric

148 suction and local shear strength for each soil material point in the unsaturated region, as cohesion is one

149 of the material properties that must be assigned during the modeling process. Eq. (6) suggests that a

150 decrease in local shear strength (the intercept of the M-C failure envelope decrease) corresponding to

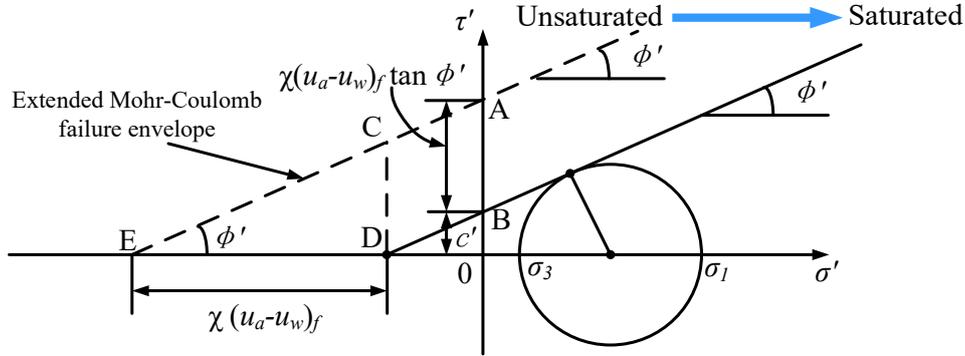

151 a decrease in matric suction during rainfall/runoff infiltration is defined by shifting the M-C failure

152 envelope towards compressive stress space as illustrated in Fig. 1. Consequently, the influences of

153 matric suction changes on the variation of the local shear strength of each soil material point in the

154 unsaturated region can be considered by using the proposed local shear strength method as shown in

155 Fig. 1.

156

157 **Fig. 1.** Local shear strength (LSS) for each unsaturated material point.

158 **3. Hybrid coupled hydro-mechanical framework and governing equations**

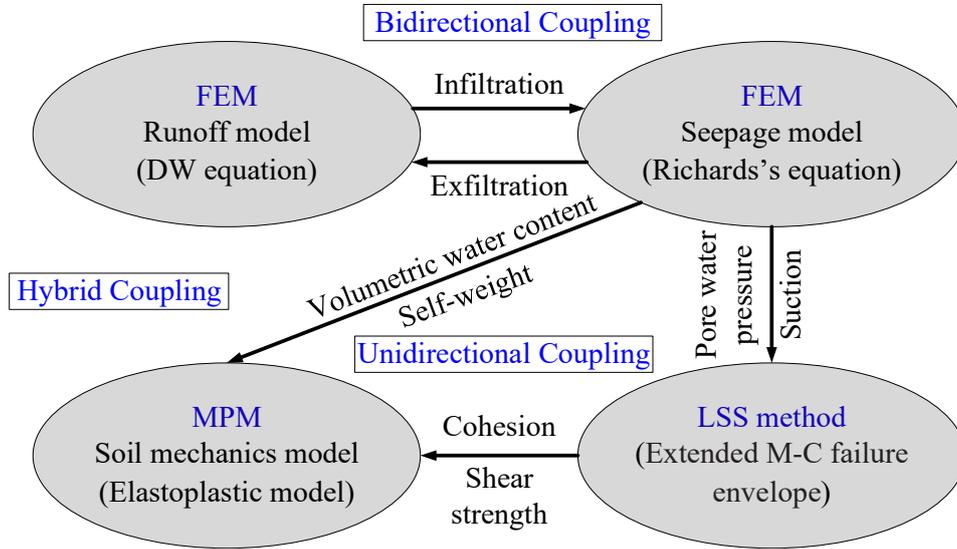

159 Based on the proposed local shear strength method, this section firstly proposes a hybrid coupled  
 160 hydro-mechanical framework of FEM and MPM to simulate runoff, seepage, and large-deformation  
 161 of the unsaturated soil slope. Then, the governing equations used in the runoff model, seepage model,  
 162 and soil mechanics model are presented.

163 **3.1 Hybrid coupled hydro-mechanical framework**

164 During a rainstorm or torrential rain, the generation of runoff has a significant impact on soil  
 165 moisture, ground surface erosion, and landslides. Meanwhile, in unsaturated soils, the variation of  
 166 volumetric water content affects matric suction, which thereby affects local shear strength. It also  
 167 affects the self-weight and stress distribution. Therefore, the effects of runoff on the soil moisture  
 168 changes, and the effects of soil moisture changes on local shear strength and self-weight of  
 169 unsaturated soil are considered in the coupled hydro-mechanical framework. In the hybrid coupled  
 170 hydro-mechanical framework, the runoff and seepage are simulated by using the PDEs (partial  
 171 differential equations) module in the FEM software, COMSOL Multiphysics (COMSOL Multiphysics,

172 2018), while the large-deformation of the landslide is simulated by using MPM3D (an MPM code that  
173 was programmed by the group led by Prof. Zhang Xiong at Tsinghua University,  
174 <http://comdyn.hy.tsinghua.edu.cn/english/mpm3d>). The coupled hydro-mechanical framework is  
175 shown in Fig. 2. The runoff model and seepage model in FEM are bidirectionally coupled through the  
176 interaction between surface water and groundwater (infiltration and exfiltration). The water depth  
177 calculated from the runoff model is applied to the seepage model as the water head boundary  
178 condition. The inflow velocity (infiltration) and outflow velocity (exfiltration) calculated from the  
179 seepage model is returned to the runoff model as the source of water. The coupling process is  
180 described in detail elsewhere (Zhu et al., 2020). The FEM analysis and MPM analysis are  
181 unidirectionally coupled in two means: (1) the influence of changes in soil moisture content (FEM  
182 output) on self-weight (MPM input) is taken into account in the elastoplastic model, and (2) the  
183 influence of matric suction (FEM output) on the local shear strength (MPM input) is considered by  
184 using the local shear strength method. It is worth noting that as shown in Fig. 2, the proposed  
185 FEM-MPM coupled model is not a fully coupled model but a hybrid coupled model. Runoff and  
186 seepage analysis is bidirectionally coupled through infiltration and exfiltration in the FEM analysis,  
187 while the FEM analysis provides inputs to the MPM analysis, meaning that this process is  
188 unidirectionally coupled. Furthermore, under the proposed framework, during the long-term coupled  
189 runoff and seepage analysis, it is assumed that the deformation of the slope is not considered because  
190 the slope is remaining stable at this time. While during the large-deformation analysis when the  
191 landslide occurs, the change of seepage force, shear strength, and pore water pressure are neglected as

192 slope failure is a quickly triggered and rapidly developing geological hazard. Therefore, these  
 193 assumptions are the limitations of the proposed coupled hydro-mechanical framework.

194  
 195 **Fig. 2.** Hybrid coupled hydro-mechanical framework of FEM and MPM.

196 3.2 Governing equation for runoff analysis

197 Runoff analysis is governed by the diffusion wave (DW) equation as shown in Eq. (7) (Weill  
 198 et al., 2009; Zhu et al., 2020),

$$199 \quad \frac{\partial h}{\partial t} - \nabla \left( \frac{h^{5/3}}{n_m \sqrt{|S|}} \nabla(H) \right) = R - I \quad (7)$$

200 where,  $I$  is infiltration/exfiltration rate (m/s);  $t$  is time (s);  $n_m$  is Manning's roughness coefficient  
 201 ( $\text{s/m}^{1/3}$ );  $h$  is runoff depth (m);  $H$  is water surface elevation (m);  $R$  is rainfall intensity (m/s);  $S$  is water  
 202 surface gradient, which can be replaced by slope gradient due to the small difference between them  
 203 (Weill et al., 2009).

204 3.3 Governing equation for seepage analysis

205 Seepage analysis is governed by the equation proposed by Richards (1931) which can be  
 206 expressed as follows,

$$207 \quad \nabla \cdot [k_s k_r \cdot \nabla(H_p + z)] + Q_w = [C_m + S_e S_c] \frac{\partial H_p}{\partial t} \quad (8)$$

208 where,  $Q_w$  is sink and source of water ( $s^{-1}$ ), which is related to  $I$ ;  $k_s$  is saturated hydraulic conductivity  
 209 (m/s);  $C_m$  is specific moisture capacity ( $m^{-1}$ );  $k_r$  is relative hydraulic conductivity;  $S_e$  is specific storage  
 210 coefficient ( $m^{-1}$ );  $H_p$  is pressure head (m);  $S_e$  is the effective degree of saturation;  $z$  is the elevation (m).  
 211 The relationship in  $C_m$ ,  $S_e$ ,  $k_r$ ,  $\theta$ , and  $H_p$  in unsaturated soil can be calculated by  $\theta_s$ ,  $\theta_r$ , and the vG  
 212 parameters,  $a$ ,  $n$ ,  $m$ , and  $l$  (van Genuchten, 1980).

$$213 \quad \theta = \theta_r + S_e(\theta_s - \theta_r) \quad (9)$$

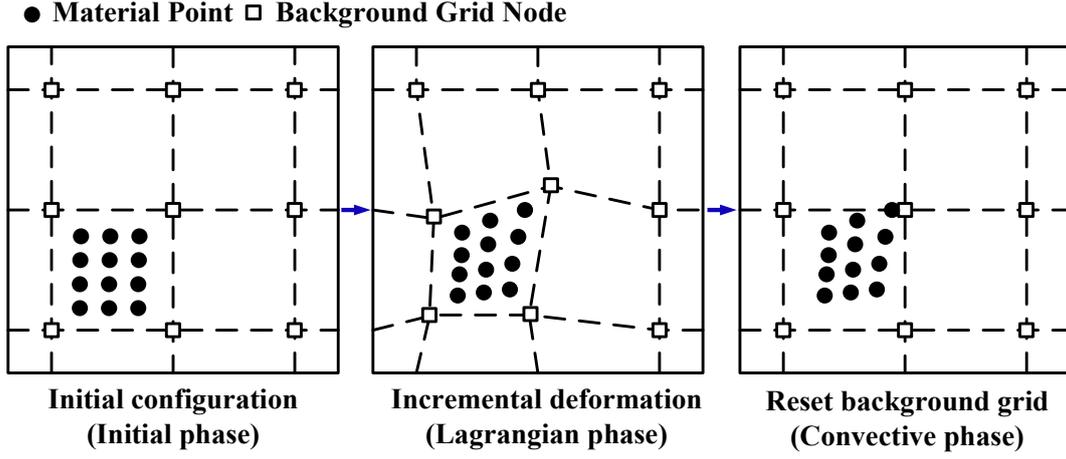

$$214 \quad S_e = \frac{1}{[1+(aH_p)^n]^m}, \quad m = 1 - \frac{1}{n} \quad (10)$$

$$215 \quad C_m = \frac{am}{1-m} (\theta_s - \theta_r) S_e^{\frac{1}{m}} (1 - S_e^{\frac{1}{m}})^m \quad (11)$$

$$216 \quad k_r = S_e^l \left[ 1 - (1 - S_e^{\frac{1}{m}})^m \right]^2 \quad (12)$$

### 217 3.4 Governing equations in MPM

218 In MPM. each computational step can be divided into three phases: initial phase, Lagrangian  
 219 phase, and convective phase as shown in Fig. 3 (Sun et al., 2015). In the initial phase, the physical  
 220 information stored in material points (e.g., locations, velocities, mass, etc.) is mapped on the  
 221 Lagrangian background grid to get the initial solution values. In the Lagrangian phase, the material  
 222 points move with the Lagrangian background grid and the global equations are solved within the  
 223 Lagrangian background grid. After that, the stored physical information is updated. In the convective  
 224 phase, the Lagrangian background grid is reset, while the stored physical information remains  
 225 unchanged.

226

227

**Fig. 3.** Three phases of one computational step of MPM (adapted from Sun et al. (2015)).

228

The governing equations of large-deformation analysis in MPM can be expressed as follows (Abe

229

et al., 2013):

230

$$\frac{d\rho(\theta)}{dt} + \rho(\theta)\nabla \cdot \mathbf{v} = 0 \quad (\text{Conservation of mass}) \quad (13)$$

231

$$\rho(\theta)\mathbf{a} = \nabla \cdot \boldsymbol{\sigma} + \rho(\theta)\mathbf{b} \quad (\text{Conservation of momentum}) \quad (14)$$

232

where,  $\rho(\theta)$  is soil-water mixture density ( $\text{kg/m}^3$ ) as a function of volumetric water content ( $\theta$ );  $\mathbf{a}$  is

233

acceleration vector ( $\text{m/s}^2$ );  $\mathbf{v}$  is velocity vector;  $\mathbf{b}$  is body forces vector ( $\text{m/s}^2$ );  $\boldsymbol{\sigma}$  is stress tensor (kPa)

234

(m/s).

235

#### 4. Validation of the proposed hybrid coupled hydro-mechanical framework

236

To check the reliability of the hybrid coupled hydro-mechanical framework proposed in this study

237

for simulating unsaturated soil slope instability, a validation model is simulated by the FEM-MPM

238

hybrid coupled model compared with the other two commonly used methods: limit-equilibrium

239

method and shear strength reduction technique. In the validation model, the water supply (rainfall and

240

runoff) is not considered. The two side walls and bottom are impermeable to water. The groundwater

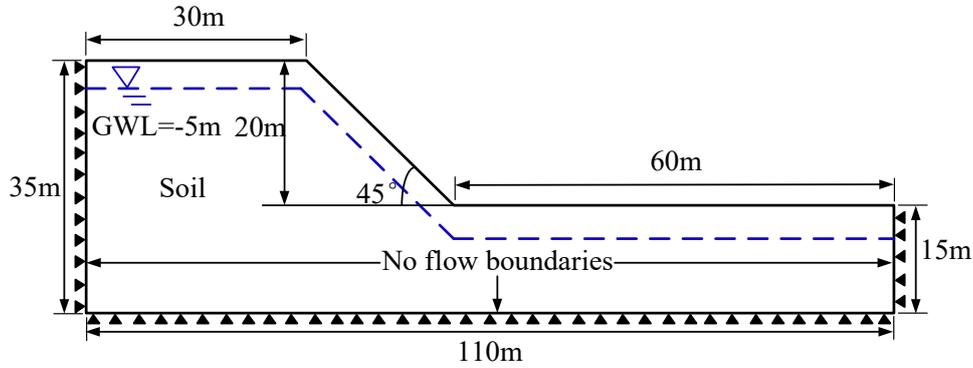

241

level (GWL) is assumed to be -5 m. Table 1 lists the soil properties used in the validation model. The

242

model size and boundary conditions are displayed in Fig. 4. The simulation results of the shear

243 strength reduction technique are obtained from COMSOL, and the simulation results of the  
 244 limit-equilibrium method are obtained from another commercial slope-stability software package  
 245 GEO-SLOPE/W (GeoStudio International, 2007).

246

**Fig. 4.** Schematic diagram of the validation model.

247

248 The comparison of the simulation results calculated by shear strength reduction technique,

249 limit-equilibrium method, and the proposed FEM-MPM hybrid coupled model are shown in Fig. 5.

250 Fig. 5(a) shows the slope in the stable state. Fig. 5(b) shows the slope in the critical state. Fig. 5(c)

251 shows the slope in the failure state. In each sub-figure (Fig. 5(a), Fig. 5(b), and Fig. 5(c)), Fig. 5(I)

252 displays the pressure head calculated by FEM. Fig. 5(II) displays the slip surface simulated by

253 limit-equilibrium method with the factor of safety (FOS). Fig. 5(III) displays the results simulated by

254 the shear strength reduction technique. Fig. 5(IV) displays the ultimate slope failure shape simulated

255 by the proposed FEM-MPM hybrid coupled model. From Fig. 5(a), it is recognized that the slope

256 simulated by the proposed FEM-MPM hybrid coupled model is stable. The FOS calculated by the

257 limit-equilibrium method (FOS=1.198) in Fig. 5(a)(II) and that calculated by the shear strength

258 reduction technique (FOS=1.190) in Fig. 5(a)(III) are larger than 1.0. From Fig. 5(b), it is recognized

259 that the slope simulated by the proposed FEM-MPM hybrid coupled model is in a critical state. At the

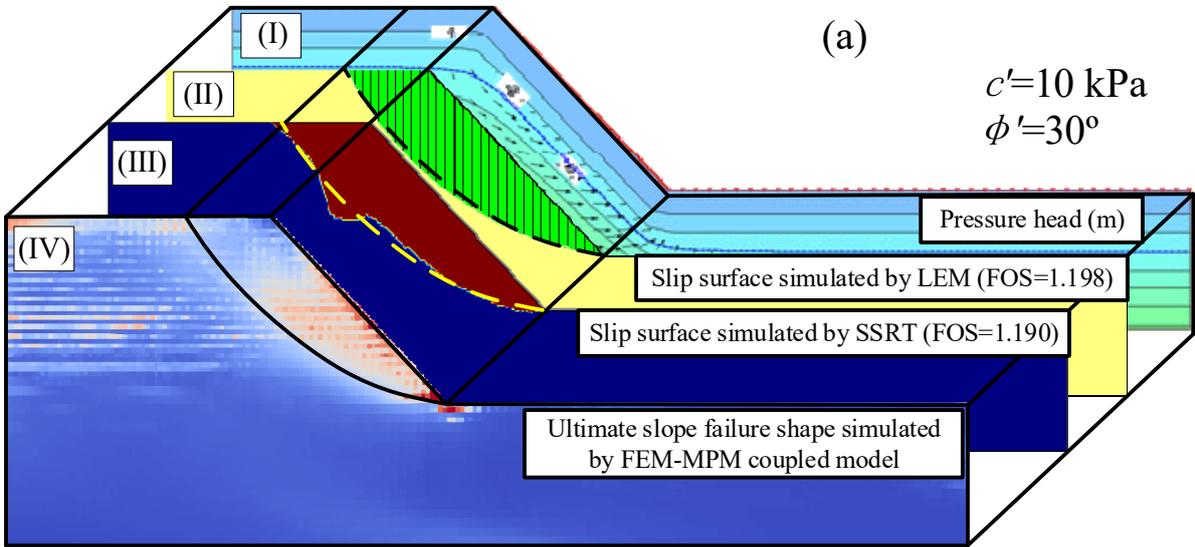

260 same time, the FOS calculated by limit-equilibrium method (FOS=0.996) in Fig. 5(b)(II) and that

261 calculated by shear strength reduction technique (FOS=0.930) in Fig. 5(b)(III) are slightly less than  
262 1.0, meaning that the slope is unstable under the pore water pressure distribution at this time. From  
263 Fig. 5(c), it is recognized that the slope simulated by the proposed FEM-MPM hybrid coupled model  
264 is failed. The FOS calculated by the limit-equilibrium method (FOS=0.567) in Fig. 5(c)(II) and that  
265 calculated by shear strength reduction technique (FOS=0.590) in Fig. 5(c)(III) are much less than 1.0.  
266 From Fig. 5(a), Fig. 5(b), and Fig. 5(c), it indicates that the slope stable/unstable state simulated by  
267 the proposed FEM-MPM hybrid coupled model is consistent with that calculated by the  
268 limit-equilibrium method and the shear strength reduction technique. The similar slip surface shapes  
269 and stable/unstable state calculated by the proposed FEM-MPM hybrid coupled model,  
270 limit-equilibrium method, and shear strength reduction technique give a good verification of the  
271 proposed FEM-MPM hybrid coupled model on simulating slope instability in unsaturated soil,  
272 although the slip surface calculated by shear strength reduction technique is slightly shallower in Fig.  
273 5(b) and Fig. 5(c). The main reason could be that the slip surface calculated by the shear strength  
274 reduction technique is the initial slip surface. Due to the calculation of the shear strength reduction  
275 technique is terminated due to non-convergence after the shallow layer is damaged, the development  
276 process of the slip surface from the initial stage to the ultimate stage is not considered by the shear  
277 strength reduction technique.

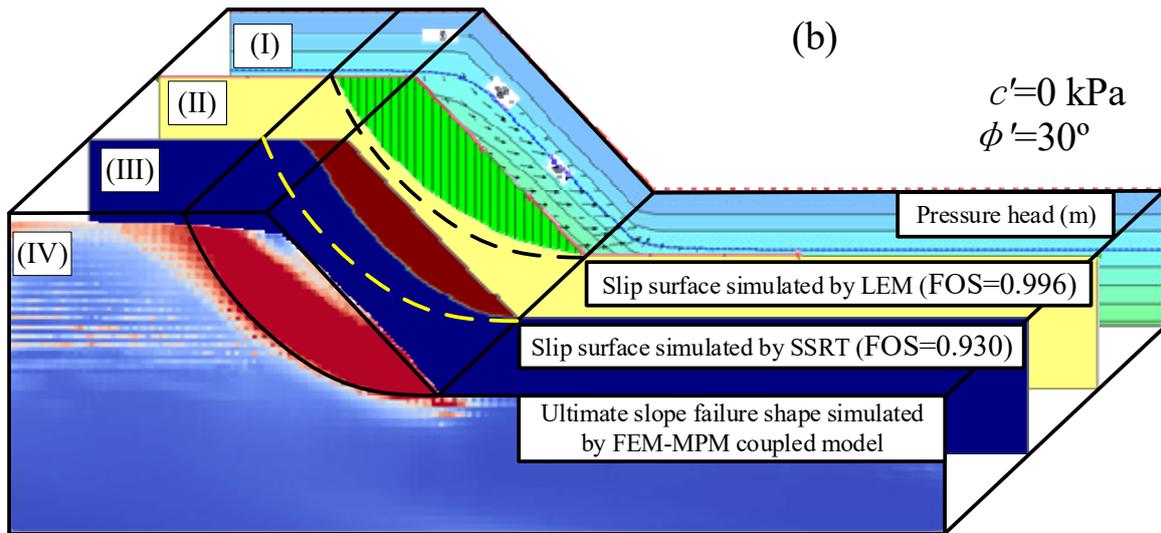

278 **Table 1** Soil properties used in the validation model.

## 287 5. Natural landslide simulation by the proposed FEM-MPM hybrid coupled model

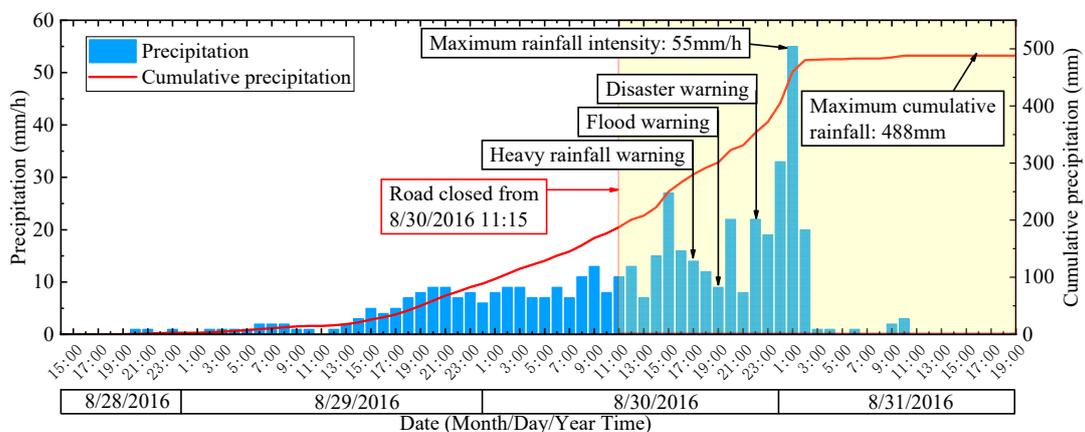

### 288 5.1 Numerical model and soil properties

289 In 2016, typhoon No.10 hit Northern Japan at the end of August. During this period, several  
 290 serious landslides occurred, for example, at location 1 in Fig. 6. The landslide is located in the Hidaka  
 291 mountains in Hokkaido, Japan. The maximum observed cumulative rainfall in three days (29<sup>th</sup>-31<sup>st</sup>)  
 292 reached 488 mm as plotted in Fig. 7. The geological conditions of this site are dominated by  
 293 metamorphic rocks and plutonic rocks that belong to the Hidaka metamorphic belt. It is mainly  
 294 composed of medium-grained and massive granite containing biotite. The shallow part of the granite  
 295 that penetrates the sedimentary rocks of the Hidaka metamorphic belt is being weathered, forming a

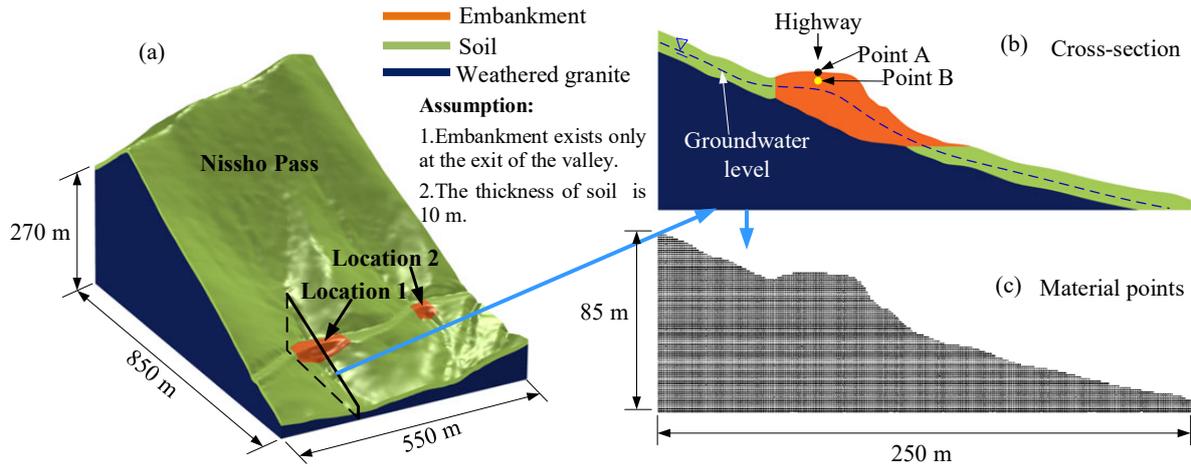

296 layer of weathered residual soil about 10 m on the ground surface. Focus on the target area  
 297 surrounded by the red dashed rectangle in Fig. 6, a three-dimensional (3D) model for runoff and  
 298 seepage analysis was built as displayed in Fig. 8(a). Fig. 8(b) displays the cross-section at Location 1.  
 299 Only one two-dimensional (2D) profile at Location 1 was simulated by the MPM model for  
 300 large-deformation analysis. Fig. 8(c) displays the material points with the number of 10,487 within the  
 301 2D profile. More simulations of 2D profiles along the sliding direction are repetitive work, so they are  
 302 not carried out in this study.

303  
 304 **Fig. 6.** Locations and performance of slope failure.

305  
 306 **Fig. 7.** Recorded rainfall during typhoon No.10.

307  
 308 **Fig. 8.** (a) 3D numerical model of the target area; (b) Cross-section at Location 1; (c) Material  
 309 points at Location 1.

310 In the 3D model, the geological composition information is shown in Fig. 8(a), and it is  
 311 considered that the embankment exists only at the exit of the valley and the thickness of the soil is 10  
 312 m. Soil properties are listed in Table 2. The parameters i.e. dry density ( $\rho_s$ ), saturated hydraulic  
 313 conductivity ( $k_s$ ), saturated volumetric water content ( $\theta_s$ ), effective cohesion ( $c'$ ), and effective friction  
 314 angle ( $\phi'$ ), Young's modulus ( $E$ ), and Poisson's ratio ( $\nu$ ) have been obtained from laboratory element  
 315 tests (Sato et al., 2017). The parameters for which no results of laboratory tests are available, i.e.,  
 316 residual volumetric water content ( $\theta_r$ ) and van Genuchten parameters ( $\alpha$  and  $m$ ) were estimated based  
 317 on the grain size curve of soil by using the software, SoilVision (SoilVision, 2018). SoilVision is  
 318 geotechnical database software that contains data on over 6,200 soil samples. It can be used to  
 319 estimate the missing characteristic values of the soil based on the grain size curve of the soil. The  
 320 initial GWL is set to -5.5 m considering historical measurements. According to the value for mountain  
 321 grassland recommended by the Japan Institute of Country-ology and Engineering (JICE), Manning's  
 322 coefficient value is set to  $0.3 \text{ s/m}^{1/3}$ .

323

## 324 5.2 Simulation results of the natural landslide induced by runoff

325 The bidirectionally coupled runoff and seepage analysis are firstly done with FEM. The  
326 simulation time (represented by  $T$ ) is a total of 70 hours from 2016-08-28 20:00 to 2016-08-31 18:00.  
327 The calculation step is set as an adaptive time-stepping scheme that means the COMSOL will  
328 automatically adjust the calculation time in each step to meet the desired Relative Tolerance (0.001 in  
329 this study). The results output time step is 1.0 hour. That is after every hour of the bidirectionally  
330 coupled runoff and seepage analysis, the volumetric water content and matric suction obtained from  
331 FEM analysis are transferred to the MPM model and used for updating the information of mass  
332 self-weight and local shear strength stored in each soil material point. From trial simulations, it is  
333 found that from 15 s after the start of the MPM analysis, the slope failure shape does not change  
334 significantly even if the calculation time is greatly increased. Therefore, the total time (represented by  
335  $t$ ) for a landslide runout simulation by MPM is set to 15 s and the calculation step is 0.2 s. Fig. 9  
336 shows the distribution of time-dependent water depth in the target area. In Fig. 9, it can be identified

337 that the overland water from the watershed is gathered at Location 1 since Location 1 is located at the  
 338 exit of the valley. The water depth exceeds 0.2 m in the upstream area of Location 1, which is much  
 339 larger than other parts of the highway. This was considered as the main cause of the landslide that  
 340 occurred at Location 1.

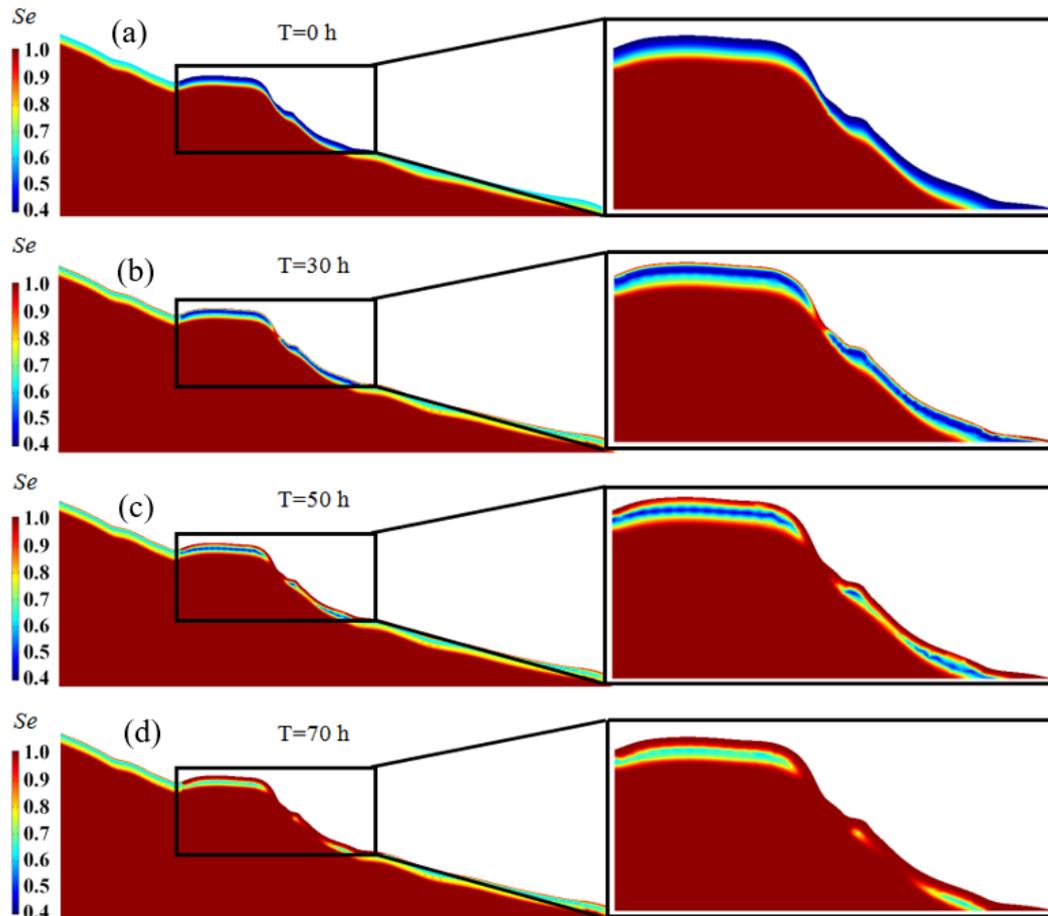

341  
 342 **Fig. 9.** Time-dependent water depth distribution at Nissho Pass (a) at  $T=10$  h; (b) at  $T=30$  h; (c)  
 343 at  $T=50$  h; (d) at  $T=70$  h.

344  
 345 **Fig. 10.** Time-dependent water depth ( $h$ ), pore water pressure ( $u_w$ ), and total cohesion intercept ( $c_f'$ ).

346 The simulated water depth ( $h$ ) at the road center (Point A in Fig. 8(b), located on the road  
347 surface), pore water pressure ( $u_w$ ), and total cohesion intercept ( $c_f'$ ) at an exploratory point (Point B in  
348 Fig. 8(b), located at 1.0 m deep below the road surface) are plotted in Fig. 10. From Fig. 9 and Fig. 10,  
349 it is identified that the generation of runoff is at 22 hours after the bidirectionally coupled runoff and  
350 seepage analysis starts. After runoff is generated, there is a dramatic increase in  $u_w$  and a sudden drop  
351 of  $c_f'$ , meaning that the generation of runoff has a remarkable influence on the matric suction and  
352 local shear strength of the embankment. Afterward, the matric suction gradually decreases to close to  
353 zero, i.e., the pore water pressure ( $u_w$ ) gradually increases to close to zero (soil is nearly saturated),  
354 causing a continuous decrease in total cohesion intercept ( $c_f'$ ) of the embankment. The decrease in the  
355 total cohesion intercept ( $c_f'$ ) leads to the decrease in the local shear strength, which causes the  
356 occurrence of the landslide. Fig. 11 shows the effective degree of saturation ( $Se$ ) at different times. It  
357 is recognized that the unsaturated soil lies above the saturated zone. The infiltration of rainwater  
358 gradually saturates the soil on the surface layer, thus resulting in the size of the unsaturated zone  
359 becoming smaller. It is also identified that after runoff is generated at  $T=22$  h, the soil on the surface  
360 layer becomes saturated at  $T=30$  h in Fig. 11 and the saturated area gradually increases with time after  
361  $T=30$  h.

362

363

**Fig. 11.** Distribution of time-dependent effective degree of saturation at Nissho Pass (a) at  $T=0$  h;

364

(b) at  $T=30$  h; (c) at  $T=50$  h; (d) at  $T=70$  h.

365

Fig. 12 shows the distribution of effective plastic strain (*EPS*) and slope failure shape with large

366

deformation at 15 s in the landslide simulation. A new MPM analysis has been run for each time with

367

different matric suction and local shear strength outputted from FEM analysis. During the MPM

368

analysis, it is assumed that the matric suction and local shear strength for each point keep constant.

369

The above assumption can be considered reasonable since the calculation of MPM is completed in

370

only 15 seconds, which is a very short time so the change of matric suction and local shear strength is

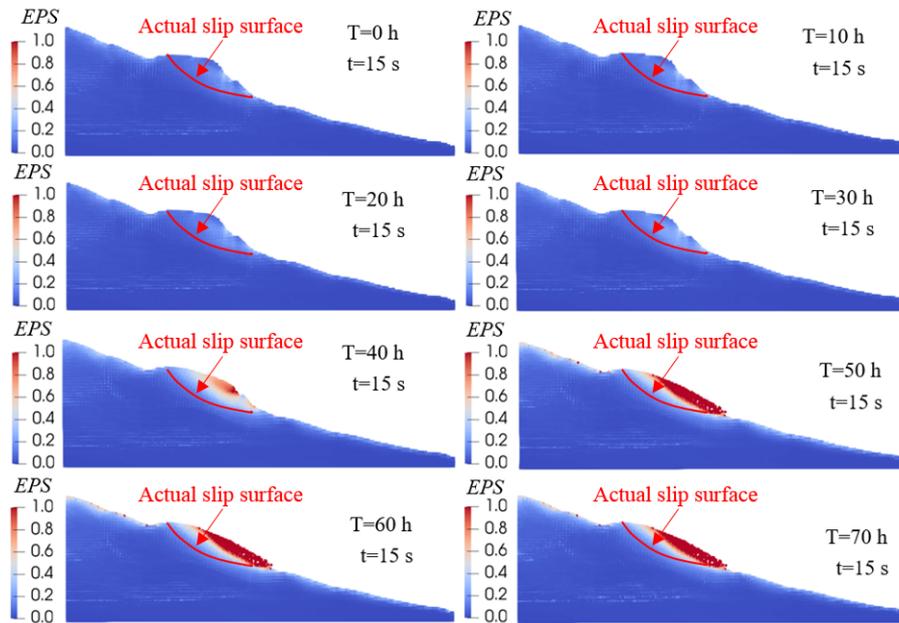

371

neglectable. From Fig. 12. it is recognized that the slope is stable before  $T=40$  h due to a large size

372

unsaturated zone lies above the saturated zone (see Fig. 11). Though high matric suction causes a high

373 local shear strength of the embankment soil, with the infiltration of rainwater, the matric suction  
 374 gradually decreases, causing a continuous decrease in local shear strength of the embankment (see Fig.  
 375 10). Finally, the slope failure occurred at approximately 40 h (the highway was closed at the same  
 376 time as shown in Fig. 10) and reached its ultimate shape between 40 h and 50 h (slope failure was  
 377 complete). Therefore, this simulation has also shown the effectiveness of the proposed hybrid coupled  
 378 hydro-mechanical framework (FEM-MPM hybrid coupled model) to reproduce and/or predict the  
 379 rainfall/runoff induced slope failure in unsaturated soil, although the simulated slip surface is  
 380 shallower compared with the actual one as shown in Fig. 12. The main reason could be that after the  
 381 occurrence of the landslide, the development of the slip surface caused by the erosion of the newly  
 382 exposed ground surface by the surface water has not been considered. This needs to be further  
 383 investigated by considering the continuous erosion of runoff in the proposed FEM-MPM hybrid  
 384 coupled model, which is one of the limitations of this study currently.

385  
 386 **Fig. 12.** Distribution of effective plastic strain and slope failure shape with large deformations at

387 Nissho Pass.

388 **6. Discussions and conclusions**

389 This paper proposes a local shear strength method for determining the variable local shear strength  
390 corresponding to the variable matric suction for each soil material point within a small catchment-scale  
391 unsaturated slope. The local shear strength method built a relationship between the variable local shear  
392 strength and the variable matric suction of each soil material point during rainfall/runoff infiltration by  
393 shifting the M-C failure envelope.

394 A hybrid coupled hydro-mechanical framework is proposed based on the local shear strength  
395 method to solve rainfall/runoff induced landslide runout in unsaturated slopes. Based on the hybrid  
396 coupled hydro-mechanical framework, a FEM-MPM hybrid coupled model is established. The  
397 landslide analysis results suggest that the slope stable/unstable state simulated by the FEM-MPM  
398 hybrid coupled model has a good consistency with the slip surface simulated by the limit-equilibrium  
399 method and shear strength reduction technique. It is proved to be also reliable to simulate the actual  
400 slope failure process to determine the occurrence time and location. Therefore, the proposed  
401 FEM-MPM hybrid coupled model is proved to be applicable for simulating rainfall/runoff-induced  
402 unsaturated soil landslide runout and has the potential to understand the location of landslide initiation  
403 and the morphological evolution.

404 These findings indicate that the local shear strength method and hybrid coupled  
405 hydro-mechanical framework proposed in this study provide a feasible way to simulate  
406 rainfall/runoff-induced landslide runout in unsaturated soil slopes. It is of great significance to  
407 evaluate the landslides movement distance and reasonably recommend the installation of barrier  
408 structures to protect the lives and properties of residents living downslope. However, the internal

409 moisture changes and the dynamic support provided by the runoff during the movement of the  
410 landslide are not considered in this study. These should be considered in the future assignments of this  
411 study.

## 412 **Acknowledgments**

413 The authors give sincere thanks to Prof. Zhang Xiong at Tsinghua University for open source their  
414 MPM3D code. Since the main works of this study were finished in Hokkaido University, the authors  
415 gratefully acknowledge the support of Hokkaido University and Hokkaido Government.
