Abstract

Waterlogging conditions cause severe abiotic stress and reduce average yields in vegetable crops. Processing tomatoes are cultivated extensively worldwide, and are used in many food products. Recently, processing tomatoes have been cultivated in paddy fields in Hokkaido, northern Japan. Studies are needed to assess the responses of processing tomatoes to wet conditions. The goal of this study was to clarify the mechanisms of waterlogging injury, and to identify ways to mitigate wet injury in processing tomatoes. We used three cultivars in a two year pot experiment and a one year field experiment. Longer waterlogging treatments increased the severity of yield losses in both experiments. The waterlogging treatments initially caused reductions in fruit number and then in average fruit weight. The reductions in fruit number resulted from reduced fruiting ratios. The reductions in average fruit weight may have been triggered by multiple factors, including reductions in soil nutrients, reduced nutrient uptake due to hypoxia, and reductions in the photosynthetic rate. These results suggested that top-dressing with fertilizer after excess rain may help to mitigate yield losses. The waterlogging treatments also induced changes in fruit composition, with reduced water content and increased sugar/acid ratios. The responses to waterlogging treatment varied among cultivars, and we concluded that 'Natsunoshun' is a superior cultivar for cultivation in converted paddy fields that may become waterlogged after heavy rains.

Key words: fruit quality, fruiting ratio, root uptake, waterlogging injury, yield

1. Introduction

Processing tomato (*Solanum lycopersicum* L.) is a widely cultivated horticultural crop that contains many functional nutrients including lycopene and β-carotene, which are vital for human health (Dorais et al., 2008). After processing, these tomatoes are consumed habitually throughout the world in a wide variety of products including ketchup, sauce, juice, and puree (Mirondo and Barringer, 2015). Approximately 38.5 million tonnes of processing tomatoes are produced per year worldwide, with major production areas in California (USA), China, Italy, and Turkey (AMITOM, 2020). Japan is one of the smallest producing countries, with about 25,200 tonnes produced in 2019 (e-Stat, 2020). Processing tomatoes are grown mainly in the central regions of Japan in Nagano and Ibaraki prefectures (e-Stat, 2020). Hokkaido, a mainly agricultural region in northern Japan, has a 200% food self-sufficiency rate, but produces only 3% of domestic processing tomatoes (e-Stat, 2020). However, interest in growing processing tomatoes in Hokkaido has recently increased because temperatures in traditional growing areas are rising due to climate change. This is a serious worldwide problem because high temperatures are a major environmental factor limiting tomato productivity (Silva et al., 2017), even in Japan (Sato, 2006). The reproductive stage appears to be especially vulnerable to temperature increases (Hedhly et al., 2009).

The numbers of farming households in Hokkaido, especially in the paddy field areas, are decreasing due to aging of the population and farmers leaving the agriculture sector. Currently, the cultivation area per farmer in Hokkaido is more than 10 times the national average, so low-cost production systems with low labor inputs are needed. To realize this goal, the National Agriculture and Food Research Organization (NARO) Bio-oriented

Technology Research Advancement Institution ran a project in Hokkaido to promote the production of processing tomatoes and onions, which can generate high crop prices even in converted paddy fields, from 2016 to 2019 (Hokkaido Agriculture Research Center (HARC/NARO), 2018). Some Hokkaido municipalities, such as Numata and Iwamizawa, already have industrial processing plants for processing tomatoes grown on converted or redundant paddy fields (Takahashi and Shiwa, 2018). However, the paddy fields generally have clay soils with quite fine particles, and are unfit for vegetable production under waterlogged conditions.

Recently, water table control systems called farm-oriented enhancing aquatic systems (FOEAS) were developed by NARO and the Paddy Research Co., Ltd. These are designed to regulate the groundwater level to an optimum depth in paddy fields, and are expected to lead to improvements in crop quality and yields (Koshiyama, 2019). Processing tomato is one of the vegetable crops that will potentially benefit from these water table control systems (Jitsuyama et al., 2019). However, it is not feasible to install these systems in all converted paddy fields, and currently, these systems are installed in less than 10% of the total available area of converted paddy fields (Jitsuyama et al., 2019). Without these systems, heavy rains are likely to produce excess moisture conditions in the clay soils of the converted paddy fields. Therefore, while water table control systems provide the best way to realize vegetable cultivation in converted paddy fields, it will also be necessary to identify cultivars with tolerance to excess moisture.

The root's activity is severely affected by salt, water deficiency, and waterlogging (Morard et al., 2000; Dresboll et al., 2013). Waterlogging results in hypoxia, which has negative effects on root development, plant growth, and longevity (Drew, 1997; Dat et al., 2004). Some research has focused on the effects of waterlogging or low oxygen

conditions on table tomatoes or wild varieties (Dresboll et al., 2013; Horchani et al., 2010; Li et al., 2012; Morard and Silventre, 1996; Opeña et al., 1992), but the effects on processing tomatoes cultivated in converted paddy fields have not been investigated. In a previous study, we conducted pot experiments with the cultivar 'Natsunoshun', which is the main cultivar grown in Numata, central Hokkaido. We found that waterlogging treatment after the first flowering stage significantly reduced yields (Jitsuyama et al., 2019).

The goal of this study was to clarify the mechanisms of waterlogging injury in processing tomatoes, and we hope that the suggestions lead to identifying ways to mitigate the waterlogging injury. For these purposes, we investigated the processing tomato's response to waterlogging treatment using three cultivars of 'Natsunoshun', 'Suzukoma' and 'Lycoball', and clarified the differences between the tested cultivars in a two-year pot experiment and a one-year converted paddy field experiment.

2. Materials and Methods

2.1. Pot experiment

2.1.1. Plant materials and plant growth

The pot experiments were performed in 2017 and 2018 in a rain shelter at the Experimental Farm of the Field Science Center for the Northern Biosphere, Hokkaido University, Sapporo, Hokkaido, Japan (N43°07'15", E141°33'87"). Three cultivars of processing tomato (*Solunum lycopersicum* L.): 'Natsunoshun', 'Suzukoma' and 'Lycoball' were tested. 'Natsunoshun' was released from the Nagano Vegetable and Ornamental Crops Experiment Station in 2004 and is a high-yielding cultivar suited to mechanized harvesting (Figure 1A). 'Suzukoma' was released from NARO in 2013 and

is suited to soilless culture systems with low node-order pinching and high-density planting (Figure 1B). ‘Lycoball’ was released from the Nagano Vegetable and Ornamental Crops Experiment Station in 2009; it is suitable for tomato juice processing and has a high lycopene content (Figure 1C). ‘Natsunoshun’ is currently the most widely grown processing tomato cultivar in Hokkaido because it is well adapted to the relatively cool summer climate (Yanokuchi et al., 2001).

From late April to early May of each year, seedlings were germinated and grown in 72-cell plug trays filled with potting soil (Nursery soil, Takii & Co., Ltd., Kyoto, Japan) that included basal fertilizer at rates of 320 $mg \cdot L^{-1}$ N, 210 $mg \cdot L^{-1}$ P_2O_5, and 300 $mg \cdot L^{-1}$ K_2O. No additional fertilizer was supplied to the pots during the experiment. These levels of fertilizer application were approximately one-tenth of the conventional levels for cultivation of ‘Natsunoshun’ (Chida et al., 2018). Eighty seedlings were used in each year for each cultivar. After germination, the apical meristems at the third leaf stage were pinched, creating two elongated lateral buds as the main stems of the plants. This is a ground creeping style of training. In early May, the seedlings were transplanted to 240 mm diameter poly-pots with the same nursery soil described above. Maintenance and insect and disease control were done according to standard practices, as described previously (Jitsuyama et al., 2019). Harvesting was done at the optimum time for each cultivar, when the fruits had matured to red (mid-September for ‘Suzukoma’, late September for ‘Natsunoshun’, and early October for ‘Lycoball’ in both years).

2.1.2. Waterlogging treatments

Four types of water stress treatments were created as follows:

CONT: each pot irrigated constantly 4–7 mm day^{-1} using irrigation pipes.

WET3: CONT conditions except for 3 consecutive days of excess soil moisture.

WET5: CONT conditions except for 5 consecutive days of excess soil moisture.

WET10: CONT conditions except for 10 consecutive days of excess soil moisture.

The WET treatments consisted of maintaining 2–3 cm of water on the soil surface. The pots had holes in the bottom to allow for drainage, so thick vinyl bags were used to prevent drainage during the WET treatments. The pots were inserted into the vinyl bags, which were held in place by additional pots (Fig. 1D). The water stress treatments were conducted at the flowering stage when 80% of plants had developed their first flower cluster. In 2017, the treatments were conducted between 17 July and 26 July [90–99 days after sowing (das)] and in 2018 they were conducted between 27 July and 5 August (86–95 das).

The following environmental parameters: soil volumetric water content, pF value, soil dissolved oxygen concentration, air and soil temperature, relative humidity, and cumulative day radiation were also measured. For these measurements, a soil moisture kit (SM150T, Delta-T Devices, Cambridge, UK), a pF meter (DIK-3162, Daiki Rika Kogyo, Co., Ltd., Saitama, Japan), a soil O_2 sensor (MIJ-03, Environmental Measurement Japan Co., Ltd., Fukuoka, Japan), a thermo recorder (R-71U, T AND D, Co., Ltd., Nagano, Japan), and an illuminance UV recorder that included a relative humidity sensor (R-74Ui, T AND D, Co., Ltd., Nagano, Japan) were used. The soil moisture was continuously measured using the kit, and the other soil measurements were conducted by inserting the O_2 sensor, thermo sensor, and pF meter into the pot soil to a depth of 15 cm. These measurements were taken once per day for each treatment, between 10:00 am and midday. The air temperature recorder and the illuminance UV recorder were each set separately

154 at 30 cm above ground which were above the tomato plants, and their data were logged
155 automatically every hour.
156
157 *2.1.3. Fruit and plant measurements*
158 At harvest time, from mid-September to early October, yield parameters (fresh fruit yield,
159 number of fruits per plant, and average weight of fruit) and fruit harvest parameters
160 (marketable fruit ratio and fruit water content) were measured. In this study, the yield
161 parameters were calculated using sepal-detached fruit, including immature fruit and fruit
162 with blossom-end rot (Fig. 1E). The marketable fruit ratio, immature fruit ratio, and
163 blossom-end rot fruit ratio were calculated using the total fruit number as the denominator.
164 The evaluation of whether or not a fruit was marketable was conducted according to the
165 standards of fruit color and size created by the Numata town tomato processors in Central
166 Hokkaido.
167 The number of flowers per plant was counted in late August, and calculated the
168 fruiting ratio using the number of flowers as the denominator. The biomass traits (root
169 and shoot dry weight, shoot water content, and leaf area) were also measured in late
170 August. The crop growth rate (CGR) was calculated using all dried biomass including
171 leaves, stems, flowers, fruits, and roots. These were measured in mid-July and again in
172 late August. The dry weights were measured after drying at 80°C for 72 hr with a forced-
173 air dryer. The leaf area of each plant was evaluated at the same times as the biomass traits
174 using a WinRHIZO system (2004a,b, Regent Instruments Inc., Canada), and converted to
175 the mean leaf area index (LAI). The net assimilation rate (NAR) was calculated as the
176 ratio CGR/mean LAI. The plant area was calculated as the area of the top of the poly-pot,
177 approximately 450 cm^2 per plant. The fruit growth rate (FGR) was calculated by using

178 the total fruit weight per plant in mid-July and in late August. The fruit delivery ratio
179 (FDR) was then calculated as FGR/CGR＊100.
180
181 *2.1.4. Statistical analyses*
182 The experimental design was a split-split plot design with five replications. Main plots,
183 subplots, and sub-subplots were defined as the two experimental years (Y: 2017 and
184 2018), the four water stress treatments (T: CONT, WET3, WET5, and WET10) and the
185 three cultivars (C: 'Natsunoshun', 'Lycoball', and 'Suzukoma'). The significance in the
186 analysis of variance (ANOVA) was calculated as described by Little and Hills (1978) for
187 the split-split plot design. Other statistical analyses, including the Student's t-test, Tukey-
188 Kramer's test and Pearson's product-moment correlation analysis were done using
189 Statcel4 (developed by Yanai, OMS, Japan), which is an add-in form in Microsoft Excel
190 2019 for Windows.
191
192 *2.2. Field experiment*
193 *2.2.1. Plant materials and growth*
194 The field experiment was performed in a converted paddy field at the Experimental Farm
195 of the Field Science Center for the Northern Biosphere, Hokkaido University, Sapporo,
196 Hokkaido, Japan (N43°07'56", E141°33'64") in 2019. We used the same three
197 experimental cultivars of processing tomato as in the pot experiment: 'Natsunoshun',
198 'Lycoball', and 'Suzukoma'.
199 The seeds were sown in late April, and the seedlings were grown as described for
200 the pot experiment. The paddy field was prepared with basal dressing chemical fertilizer
201 (N:P:K=15:20:40 kg/10a) and plowed to a 20 cm depth. Elongated mounds of 110 cm

202 width and 20 cm height were created mechanically and covered with biodegradable black
203 mulching film (Kiemaru, Unyck, Tokyo, Japan). The seedlings were planted with spacing
204 of 50 cm along the top of each mound. No top dressing was added during the cultivation.
205 Bird repelling nets were used to protect the fruits (Fig. 1F). Harvesting was done at the
206 optimum time for each cultivar: on 12 September (147 das) for 'Suzukoma', on 18
207 September (153 das) for 'Natsunoshun', and on 26 September (161 das) for 'Lycoball'.
208 Maintenance and insect and disease control were done according to standard practices, as
209 described previously (Jitsuyama et al., 2019).
210
211 *2.2.2. Waterlogging treatments and measurements*
212 Three types of water stress treatments were created as follows:
213 CONT: field with natural precipitation (pF value greater than 2.0).
214 WET5: CONT conditions except for 5 consecutive days of excess irrigation.
215 WET10: CONT conditions except for 10 consecutive days of excess irrigation.
216 The WET treatments consisted of keeping the soil surface wet (pF value less than 1.7;
217 Fig. 1G) and were conducted between 10 July and 19 July (83–92 das) at the flowering
218 stage when 80% of plants had developed their first flower cluster. The waterlogging
219 treatments were done using irrigation pipes near the planted mounds, and partitions
220 between treatments were created by inserting plastic boards to a depth of 30 cm. The ten
221 acre paddy field has a slight slant from the inlet to the outlet, and the treatments were
222 ordered from the inlet as follows: CONT, WET5, WET10.
223 The environmental parameters (soil volumetric water content, pF value, soil
224 dissolved oxygen concentration, air and soil temperature, relative humidity, cumulative
225 day radiation) were measured as described for the pot experiment. At harvest, the yield

parameters (fresh fruit yield, number of fruits per plant, and average weight of fruit) and fruit harvest parameters (marketable fruit ratio and fruit water content) were also measured as described for the pot experiment.

Soil components, soil properties, and soil microbial activity (see Table S2) were also measured before and after the waterlogging treatments. Three soil samples of 500g wet weight were taken from the center of the mound 25 cm from plants in each treatment area. The analyses were conducted by the Tokachi Federation of Agricultural Cooperatives.

A fruit composition analysis was conducted as described previously (Jitsuyama et al., 2019). Each replication was done using four fruits from a plant at harvest, and the average value of the four fruits was defined as the value of the replication. In summary, half of each fruit was squeezed to get the sap and juice, which were used to measure Brix and acidity with a Brix-acid meter (PAL-BX/ACID F5 Master Kit; ATAGO Co., Ltd., Tokyo, Japan). The other half of the fruit was freeze-dried and powdered, and 25 mg of each powdered sample was homogenized, extracted in hexane, dried, and re-mobilized in 100 μL chloroform and 900 μL acetonitrile. Then, 20 μL of the mixture was analyzed by high performance liquid chromatography to determine the lycopene and β-carotene contents, as described by Jitsuyama et al. (2019). The Beer-Lambert law was used to calculate the contents.

2.2.3. Statistical analysis

The experimental design was a split plot design with five replications (five plants per replication). The main plots and subplots were defined as the three water stress treatments (T: CONT, WET5, and WET10) and the three cultivars (C: 'Natsunoshun', 'Lycoball' and 'Suzukoma'). The significance in the ANOVA was calculated as described for the

split-split plot design (Little and Hills, 1978). Other statistical analysis was done as described for the pot experiment.

3. Results

3.1. Pot experiment

3.1.1. Environment

When the air temperatures were averaged over the entire 6 months' duration of the pot experiment, they did not differ between years (2017: 19.7˚C, 2018: 19.2˚C, Student's t-test, $p>0.1$) (Table S1). However, during the 12-day period just before flowering (5–16 July), the average air temperature was higher in 2017 than in 2018 (2017: 25.0˚C, 2018: 18.5˚C, Student's t-test, $p<0.001$). The average total solar radiation over the 6-month duration of the experiment was also higher in 2017 than in 2018 (2017: 17.0 MJ・m^{-2}, 2018: 15.1 MJ・m^{-2}, Student's t-test, $p<0.05$).

The waterlogging treatments drastically altered the soil environments, including the water content, pF value, and oxygen concentration (Table S1). The average soil water contents during the waterlogging treatments were significantly higher than in the controls (2017; CONT: 16.6%, WET: 42.5%, 2018; CONT: 17.6%, WET: 42.9%, Tukey-Kramer's test, $p<0.05$). The soil water content affected the average pF values such that the pF values in the waterlogging treatments were significantly lower than in the controls (2017; CONT: 1.94, WET: 1.32, 2018; CONT: 1.86, WET: 1.33, Tukey-Kramer's test, $p<0.05$). Similarly, the soil water content affected the average oxygen concentrations, with significantly lower oxygen concentrations in the waterlogging treatments than in the controls (2017; CONT: 16.3%, WET: 0.6%, 2018; CONT: 18.2%, WET: 0.9%, Tukey-

274 Kramer's test, $p<0.05$). For the data shown here, the daily measurements in the WET10,
275 WET5, and WET3 treatments (a total of 18 measurements) were used to calculate the
276 WET means, and 10 daily measurements in the CONT treatment were used to calculate
277 the CONT means.
278
279 *3.1.2. Yield-related traits*
280 The yield-related data from the pot experiment and the ANOVA used to compare the
281 variables among experimental years, waterlogging treatments, and cultivars are shown in
282 Table 1. The only significant effect of the experimental year was on yield ($p<0.05$); the
283 yield in 2018 was lower than in 2017. The waterlogging treatments also significantly
284 affected yields ($p<0.001$), and longer waterlogging treatments caused greater yield
285 reductions. There were also significant effects of cultivar on yield ($p<0.01$), with the
286 greatest yields from 'Natsunoshun' and the lowest yields from 'Lycoball'.
287 The waterlogging treatments also affected the number of fruits per plant ($p<0.01$),
288 causing reduced numbers regardless of the duration of the treatment. The number of fruits
289 per plant was also affected by cultivar ($p<0.001$), with 'Suzukoma' producing the largest
290 numbers and 'Lycoball' producing the fewest. Based on the Tukey-Kramer's test
291 ($p<0.05$), the average weight was reduced by waterlogging treatment for 5 days or more.
292 The average weight was significantly lower in 'Suzukoma' than in other two cultivars
293 ($p<0.05$).
294 The relationships between yield and number of fruits per plant and between yield
295 and average weight of fruit are shown for each cultivar in Figure S1A–C. All cultivars
296 showed significant relationships between both pairs of traits ($p<0.001$), however the
297 correlation coefficients were different among cultivars. The correlation between yield and

298 number of fruits per plant was strongest in ‘Lycoball’, whereas the correlation between
299 yield and average weight of fruit was strongest in ‘Suzukoma’.

300 The waterlogging treatments and cultivar each significantly affected the marketable
301 fruit ratio. The WET5 and WET10 treatments produced lower ratios than the CONT and
302 WET3 treatments (p<0.001), and ‘Suzukoma’ had a higher ratio than the other two
303 cultivars (p<0.001) (Table 1). The fruit water content was reduced by waterlogging
304 treatment for 5 days or more, and was lower in ‘Lycoball’ than in the other two cultivars
305 (Tukey-Kramer’s test, p<0.05).

306 The ANOVA analysis revealed significant interactions among experimental year,
307 waterlogging treatment, and cultivar that affected both yield and the number of fruits per
308 plant (p<0.05) (Table 1). There were also significant interactions between experimental
309 year and cultivar that affected yield (p<0.01). The effect of experimental year was
310 strongest in ‘Lycoball’, since the ‘Lycoball’ yield was significantly reduced in 2018
311 compared with 2017 (Figure 2A). The negative effects of waterlogging treatment on yield
312 were similar between both years and among all three cultivars, except in the ‘Suzukoma’
313 CONT-treated plants in 2017. That year, the CONT-treated ‘Suzukoma’ plants had
314 relatively low yields, similar to those of the WET5-treated plants (Figure 2B). There
315 tended to be no clear effects of the waterlogging treatments on the number of fruits per
316 plant, except for a slight negative effect on ‘Natsunoshun’ in 2017 and a stronger negative
317 effect on ‘Suzukoma’ in 2017 (Figure 2C).

318

319 *3.1.3. Flowering and fruiting ratio*

320 The numbers of flowers per plant and the fruiting ratios in the pot experiment, along with
321 the ANOVA results, are shown in Table 2. The experimental year had significant effects

on the number of flowers (p<0.001) and the fruiting ratio (p<0.05), with more flowers per plant but lower fruiting ratios in 2017 than in 2018. The waterlogging treatment significantly and negatively affected the fruiting ratio (p<0.01) but didn't significantly affect the number of flowers per plant. The number of flowers per plant was significantly affected by cultivar (p<0.01), with 'Suzukoma' having the highest number and 'Lycoball' the lowest. There were no significant interactions among year, treatment, and cultivar in their effects on the number of flowers per plant. The only significant interactions affecting fruiting ratio were between experimental year and cultivar (p<0.05), and between waterlogging treatment and cultivar (p<0.05) (Table 2). The fruiting ratio in 2018 was greater than in 2017 in 'Natsunoshun' and 'Suzukoma' at significance levels of 5% and 1%, respectively (Fig. 3A). The waterlogging duration affected the fruiting ratios differently among cultivars: ratios were significantly reduced by three or more days of waterlogging treatment in 'Natsunoshun', five or more days in 'Lycoball', and ten days in 'Suzukoma' (Fig. 3B).

3.1.4. Plant biomass

The root dry weight, shoot dry weight, shoot water content, leaf area, net assimilation rate (NAR) and fruit dry matter distribution ratio (FDR) data from the pot experiment, along with the ANOVA results, are shown in Table 3. The only significant effect of experimental year was on the FDR (p<0.01): the FDR was higher in 2017 than in 2018. The waterlogging treatments had significant effects on root dry weight, shoot dry weight, leaf area, and FDR at the 0.1% significance level. All traits, including the shoot water content and the NAR, were reduced by the longer waterlogging treatments. The cultivar also significantly affected four traits: root and shoot dry weight, leaf area, and FDR.

346 ‘Natsunoshun’ had the largest shoot dry weights (p<0.001) and leaf areas (p<0.001);
347 ‘Lycoball’ had the largest root dry weights (p<0.05); and ‘Suzukoma’ had the highest
348 FDR among all cultivars (p<0.001).

349 There were significant interactions between experimental year and treatment in their
350 effects on root dry weight (p<0.05) and leaf area (p<0.01). In 2017, the root dry weight
351 was reduced by waterlogging treatment for 3 or more days, however in 2018, 5 or more
352 days of treatment were needed to reduce the root dry weight (Fig. 4A). The leaf area was
353 similarly affected by year and treatment except that in 2018, 10 days of treatment were
354 needed to significantly reduce leaf area (Fig. 4B). A significant interaction between
355 experimental year and cultivar was detected for the FDR (p<0.01). The FDRs of
356 ‘Natsunoshun’ and ‘Lycoball’ were lower in 2018 than in 2017, but there was no
357 significant change for ‘Suzukoma’ (Fig. 4C). In root dry weight, there was a significant
358 interaction between treatment and cultivar (p<0.05). The root dry weights of ‘Lycoball’
359 and ‘Suzukoma’ were reduced by the longer waterlogging treatments, however, that of
360 ‘Natsunoshun’ was not affected by the treatment (Fig. 4D).

361

362 *3.2. Paddy field experiment*

363 *3.2.1. Environment*

364 The average air temperature in the paddy field during the summer of 2019 was 20.3˚C,
365 and the average total solar radiation was 17.7 MJ・m^{-2} (Table S1). The average air
366 temperature and total solar radiation during the waterlogging treatments at flowering (10–
367 19 July) were 20.7˚C and 18.6 MJ・m^{-2}, and these were not significantly different from
368 the averages for the total duration of the experiment (p>0.1, Student’s t-test).

As we found in the pot experiment, the waterlogging treatment changed the following soil parameters: the water content, pF value, and oxygen concentrations (Table S1). The average soil water contents were increased significantly by waterlogging [CONT: 13.9%, WET5: 31.5%, WET10: 41.3%, Tukey-Kramer, $p<0.05$ (CONT; n=42, WET5; n=5, WET10; n=10)]. The average pF values were significantly lowered by waterlogging [CONT: 2.11, WET5: 1.16, WET10: 1.09, Tukey-Kramer, $p<0.05$ (CONT; n=121, WET5; n=5, WET10; n=10)]. The average oxygen concentrations were also significantly lowered [CONT: 19.3%, WET5: 14.2%, WET10: 15.1%, Tukey-Kramer, $p<0.05$ (CONT; n=41, WET5; n=5, WET10; n=10)]. On the other hand, the soil temperatures at depths of 10 cm and 20 cm were not affected by the waterlogging treatments ($p>0.1$ CONT; n=10, WET5; n=5, WET10; n=10).

The soil component in field experiment before and after flooding treatment are shown in Table S2. The waterlogging treatments had significant effects on the pH, soluble zinc, hot water soluble boron and total nitrogen, but not on the other composition, soil property and microbial activity. The soils in WET5 and WET10 had significantly lower soluble zinc, hot water soluble boron and total nitrogen than soil in control ($p<0.05$), and significantly higher pH than the control soil ($p<0.05$).

3.2.2. Yield and parameters related to yield

The data related to yield in the field experiment (yield, number of fruits per plant, average weight of fruit, marketable fruit ratio, and fruit water content), along with the ANOVA results, are shown in Table 4. The waterlogging treatments significantly affected all of these parameters. The WET10 plants had lower yields than the other treatments ($p<0.001$), the WET5 and WET10 plants had lower numbers of fruits per plant ($p<0.01$), and the

393 WET10 plants had lower average fruit weights (p<0.001). These parameters were also
394 affected by cultivar. ‘Natsunoshun’ had the highest yields while ‘Suzukoma’ had the
395 lowest (p<0.001), ‘Lycoball’ had the lowest number of fruits per plant (p<0.01), and
396 ‘Suzukoma’ had the lowest average fruit weight (p<0.001).

397 The relationships between fruit yield and number of fruits per plant and between
398 fruit yield and average weight of fruit are shown for each cultivar in Fig. S2.
399 ‘Natsunoshun’ and ‘Lycoball’ showed the strongest correlations between fruit yield and
400 number of fruits per plant (number of fruits: p<0.001, weight of fruits: p<0.05). On the
401 other hand, ‘Suzukoma’ showed the strongest correlation between fruit yield and average
402 weight of fruit (number of fruits: p<0.01, weight of fruits: p<0.001).

403 The marketable fruit ratios and fruit water contents were also affected by
404 waterlogging treatment and cultivar. The WET10 plants had lower marketable fruit ratios
405 and fruit water contents than those in the other treatments (p<0.001). Among the cultivars,
406 ‘Lycoball’ had the lowest marketable fruit ratio (p<0.001) and ‘Suzukoma’ had the lowest
407 fruit water content (p<0.001). The ANOVA did not reveal any interactions between
408 waterlogging treatment and cultivar in any of the traits related to yield.

409 The reduced yields and parameters related to yield in the WET-treated plants may
410 have been due, at least in part, to reduced transpiration rates. During the waterlogging
411 treatments, we observed that the plants became wilted after around 5 days of waterlogging
412 treatment (Fig. S3A and B). We did not measure root dry weights in the field experiment,
413 but the development of adventitious roots in the WET-treated plants (Fig. S3C and D)
414 suggested that the plants were responding to reduced efficiencies in the function of the
415 below-ground roots.

416

3.2.3. Fruit composition

The fruit composition parameters: brix, acidity, sugar/acid ratio, and lycopene and β-carotene contents of the field-grown tomatoes, along with the ANOVA results for these parameters, are shown in Table 5. The waterlogging treatments had significant effects on the brix levels and the sugar/acid ratios, but not on the other parameters. The WET10 plants had significantly higher brix levels ($p<0.001$) and sugar/acid ratios ($p<0.01$) than the CONT plants. The cultivars had significant effects on brix, acidity, sugar/acid ratio, and β-carotene content. 'Suzukoma' had the highest brix level among the cultivars ($p<0.001$) and 'Lycoball' had the highest acidity ($p<0.001$). The sugar/acid ratios differed significantly among all three cultivars, with the highest in 'Suzukoma' and the lowest in 'Lycoball' ($p<0.001$). The β-carotene content was highest in 'Lycoball' ($p<0.001$). No interactions were found by ANOVA between treatment and cultivar in their effects on the brix, acidity, or sugar/acid ratios, however, significant interactions were detected in their effects on the lycopene ($p<0.05$) and β-carotene ($p<0.01$) contents. The lycopene contents were increased by longer waterlogging treatments in 'Lycoball', but not in the other two cultivars (Fig. 5A). Conversely, the β-carotene contents in 'Natsunoshun' and 'Suzukoma' were increased by longer waterlogging treatments, but that of 'Lycoball' did not change (Fig. 5B).

3.2.4. Fruit quality

Fruit quality data for the field cultivated tomatoes, along with the ANOVA results for those variables, are shown in Table 6. The waterlogging treatments had significant effects on the marketable fruit ratio and the immature fruit ratio, but not on the blossom-end rot fruit ratio. The WET10 plants had significantly lower marketable fruit ratios than plants

441 in the other treatments (p<0.001), and significantly higher immature fruit ratios than the
442 WET5 plants (p<0.001). 'Lycoball' had a much lower marketable fruit ratio than the
443 other two cultivars (p<0.001), whereas 'Suzukoma' had a much lower immature fruit ratio
444 than the other two cultivars (p<0.001). The ANOVA detected significant interactions
445 between treatment and cultivar in their effects on immature fruit ratio and blossom-end
446 rot fruit ratio (p<0.01). The blossom-end rot fruit ratio was increased by the waterlogging
447 treatments in 'Natsunoshun' and 'Lycoball', but not in 'Suzukoma' (Fig. 6A). Similarly,
448 the immature fruit ratio was increased by the longer waterlogging treatment in
449 'Natsunoshun' and 'Lycoball', but not in 'Suzukoma' (Fig. 6B).
450
451
452 **4. Discussion**
453 *4.1. What kinds of environment aggravate the processing tomatoes' wet injury?*
454 The wet conditions used in this study drastically reduced the fruit yield of processing
455 tomatoes in both the pot and converted paddy field experiments (Table 1, Table 4). An
456 important question is, what kinds of environmental factors affect the severity of the wet
457 injury? The soil types, temperature and radiation could also be impactful factors, however,
458 a very clear result from this study was that the longer the waterlogging treatment, the
459 greater the effect on yield. The 10-day waterlogging treatment in the converted paddy
460 field and the 3-day waterlogging treatment in the pot experiment significantly reduced
461 yields. In previous studies, severe damage and yield reductions were reported after 3 to 5
462 days of wet conditions in the field (Jitsuyama et al., 2019; Higashio et al., 2012).
463 Our biomass analysis in the pot experiment showed that 3 days of waterlogging
464 treatment reduced the root and shoot biomass and leaf area, and prolonged treatment was

465 linked to smaller plant size (Table 3). We also found interactions between experimental
466 year and treatment in both root dry matter and leaf area: the effect of the waterlogging
467 treatment was greater in 2017 than in 2018 (Fig. 4A, B). Therefore, environmental
468 differences between the two years might provide information on what environmental
469 factors can aggravate the tomatoes' wet injury.

470 In the pot experiment, the water treatments were the same between years, and the
471 profiles of the air temperature and the accumulated light intensity were similar between
472 years. Therefore, the greatest environmental difference between 2017 and 2018 was in
473 the average temperatures from early July to mid-August; temperatures during this period
474 were higher in 2017 than in 2018. Possibly, these higher temperatures aggravated the
475 yield reduction due to waterlogging. In the case of soybeans, if the ambient temperature
476 was higher, the wet injury became more severe (Jitsuyama, 2013; Matsukawa et al., 1983).
477 It has also been shown that in tomatoes, heat and waterlogging are the two biggest
478 challenges to production (Opeña et al., 1992).

479 The value of growth ratio per leaf area, NAR, was reduced by waterlogging
480 treatment for more than 5 days (Table 3). Although it was not significant, the NAR was
481 lower in 2017 than in 2018 at a specific period, possibly because the water available for
482 photosynthesis was limited by the hotter weather. Tomato fruits after fruit set are the
483 strongest sink organs (Wardlaw, 1990). The waterlogging treatment reduced not only the
484 source organs, the leaves, but also the FDR (Table 3). The excess moisture also drastically
485 reduced the root dry weight (Table 3). These results suggest that the higher temperatures
486 may have aggravated the tomatoes' wet injury because the smaller roots could not satisfy
487 the higher transpiration demands. This phenomenon would lead to reduced
488 photosynthetic efficiency and reduced translocation.

Both fruit number and fruit size contribute to yield. We found that in the pot experiment, fruit number was reduced after only 3 days of waterlogging, whereas fruit size was not reduced unless the plants were exposed to 5 or more days of waterlogging (Table 1). Similarly, in the field experiment a shorter period of waterlogging was needed to reduce the fruit number than was needed to reduce the average weight of the fruit (Table 4). These results suggest that fruit number is more sensitive to waterlogging than fruit size. In brief, the facts support the hypothesis that excess moisture affects how many flowers develop into fruits.

The fruit number is determined by flower number and the number of flowers that develop into fruit. The ANOVA showed that the waterlogging treatment affected the fruiting ratio more than it affected the number of flowers (Table 2). Thus, the fruit number was reduced because fewer flowers developed into fruits. In a previous study using only 'Natsunoshun', the fruit number was more closely related to the fruiting ratio than to the number of flowers (Jitsuyama et al., 2019). We did not detect an interaction between experimental year and treatment in their effects on the number of flowers or the fruiting ratio (Table 2), so it is difficult to explain what environmental factors might aggravate the tomatoes' lower fruiting ratio after waterlogging.

4.2.What kinds of tomato traits tend to aggravate wet injury?

Next, we considered what kinds of tomato cultivar traits might aggravate wet injury. In particular, we focused on the specific traits that were linked to the lower fruiting ratios after waterlogging. The fruits of 'Suzukoma' were relatively small (average weight less than 40 g per fruit) but it had relatively large numbers of fruits per plant and marketable fruit ratios (Table 4, Fig. 1B). Therefore, the relationship between yield and yield

components differs between ‘Suzukoma’ and the other two cultivars (Fig. S1). The other cultivars, ‘Natsunoshun’ and ‘Lycoball’, produce relatively large fruits of more than 70 g per fruit (Table 4). The total yield of ‘Natsunoshun’ was larger than that of ‘Lycoball’, because the fruit number per plant affected the yield (Table 1, Table 4). All three cultivars showed interactions with waterlogging treatment (cultivar x treatment) in their effects on fruiting ratio (Table 2), but ‘Natsunoshun’ was more sensitive than the other two (Fig. 3B). The results indicate that the yield reduction in ‘Natsunoshun’ after waterlogging was largely due to the reduction in fruiting ratio. In the pot experiment, the difference in yield between the CONT and WET3 treatments was significant in 2017 but not in 2018, in both ‘Natsunoshun’ and ‘Lycoball’ (Fig. 2B). The total yield in 2017 was much higher than in 2018 (Table 1), and thus, the results show that the effect of waterlogging was exaggerated in the high-yield year.

The ANOVA results showed that one of the parameters whose interaction between treatment and cultivar was significant is the root dry weight (Table 1). Whereas the fruiting ratio in ‘Natsunoshun’ was more sensitive to waterlogging than it was in the other two cultivars (Fig. 3B), the other two cultivars showed more sensitivity to waterlogging in their root dry weights (Fig. 4D). Therefore, there appeared to be no relationship between the fruiting ratio reduction and the stress-responsiveness of the root biomass. On the other hand, it is possible that the nutritional status of the plant may affect the fruiting ratio. Cultivation under low nutrient conditions resulted in incomplete flower development, smaller ovaries, and higher rates of flower abscission in tomato (Saito and Ito, 1967). The waterlogging treatment in the field experiment significantly reduced the total nitrogen and nitrate contents of the soil (Table S2). This was likely due to denitrification by anaerobic bacteria (Nishio, 1994) and of the leaching of nitrogen by

537 excess moisture (Tokuda, 2018). One of the main factors contributing to yield reduction
538 in tomato is nitrogen deficiency (Higasa and Imada, 1993), and nutritional uptake of the
539 root depends on the oxygen concentration at the root zone (Morard and Silventre, 1996).
540 Thus, even before the root biomass was affected by waterlogging, the treatment caused a
541 reduction in nutrient uptake by the roots under the low oxygen conditions, and a reduction
542 in nitrogen availability. Therefore, topdressing of nitrogen just after waterlogging may be
543 affective in mitigating the wet injury. Previous studies in wheat and soybean have also
544 shown that nitrogen topdressing is effective in the mitigation of wet injury (Sugimoto et
545 al., 1988).

546 There was no significant interaction between treatment and cultivar in any other
547 parameter related to biomass, however, we detected significant interactions in the
548 immature fruit ratio and the blossom-end rot fruit ratio (Table 6). In our previous study,
549 the reduction in the marketable fruit ratio caused by waterlogging was accompanied by
550 reductions in the blossom-end rot fruit and immature fruit ratios (Jitsuyama et a., 2019).
551 In this study, ‘Natsunoshun’ and ‘Lycoball’ showed increased immature fruit and
552 blossom-end rot fruit ratios after waterlogging (Fig. 6-A, B). Generally, blossom-end rot
553 in tomato is induced by calcium deficiency (Manishi et al., 1996). We detected no
554 significant changes in the exchangeable calcium content of the soil after waterlogging,
555 but we did find changes in the boron content (Table S2). Boron affects calcium uptake
556 and utilization in the plant body (Bose and Tripathi, 1996). Therefore, the frequency of
557 blossom-end rot may have been affected by the lower soil boron content after
558 waterlogging. Our previous study showed that a lack of moisture may delay fruit
559 maturation and increase morbidity due to blossom-end rot (Jitsuyama et al., 2019). This
560 suggests that a declined water uptake in the root may have increased the immature fruit

and blossom-end rot ratios in ‘Lycoball’, since the root mass of ‘Lycoball’ was reduced by the waterlogging treatment (Fig. 4D). In summary, the delayed maturation and morbidity due to blossom-end rot may be caused by both root mass reduction and root malfunction resulting from hypoxia.

4.3. Root mass reduction by wet injury

As mentioned above, the root malfunction due to hypoxia must be considered the first step in the wet injury of processing tomato, because root mass reduction had not occurred when the waterlogging treatment began. Generally, the root system is the first organ to be affected by physiological stress under waterlogging conditions (Drew,1997; Dat et al., 2004), and the phenomenon is accompanied by oxidative damage (Li et al., 2012) under the changes of soil microbiota and soil redox potential (Moriyama et al., 2018). This damage induces root rot, which limits the uptake of water and nutrients, and these biological disorders result in biomass reduction (Ma et al., 2005). Five days of waterlogging conditions severely hampered root elongation in table tomato (Dresboll et al., 2013). Root rot may cause localized increases in carbon dioxide, methane gas, and volatile fatty acids produced by fermentative metabolic processes (Pezeshki, 2001). We did detect a foul odor from the root systems of the waterlogged plants, whose root dry weights were drastically reduced by the waterlogging treatments (Table 3).

As described above, the fruiting ratio might be less affected by root damage, however, the reduction in water uptake must affect translocation to the fruits, eventually affecting fruit size. The leaves under the waterlogging treatment showed severe wilting symptoms (Fig. S3A, B), and the water contents in the stem and fruit were also reduced after prolonged waterlogging conditions (Table 1, Table 3). These data provide evidence

585 of reductions in water uptake. From the viewpoint of root biomass, ‘Natsunoshun’ was
586 less affected by the excess moisture, and may have physiological or morphological traits
587 that reduce the negative effects of waterlogging. The results also suggested that the other
588 cultivars which have larger roots could also have higher root plasticity leading to
589 adaptations to waterlogging. From a different angle, however, ‘Natsunoshun’, with its
590 small root system, has superior stability against waterlogging in another way. There is a
591 soybean cultivar whose root system is quite small, but its wet tolerance is markedly strong,
592 and expresses no reduction in hypoxia (Jitsuyama, 2017). Some tomato cultivars can
593 adapt to excess soil moisture by growing adventitious roots, triggered by anoxia or
594 hypoxia (Jackson and Drew,1984; Colmer and Voesenek, 2009). In this study,
595 adventitious roots were found at the bases of stems after 3 days or more of waterlogging
596 (Fig. S3C, D), however, we did not observe differences among cultivars in the frequency
597 of adventitious root formation.
598
599 *4.4. Effects of waterlogging on fruit composition*
600 We found that the fruit water contents decreased significantly with longer waterlogging
601 treatments (Table 1, Table 4), and this tendency was similar to the reductions in average
602 fruit weight after waterlogging. The results suggest that the reduction in fruit size by
603 waterlogging was caused by the reduction in water translocation to the fruits. Moreover,
604 in the field experiment, the fruit sugar/acid ratio increased with longer waterlogging
605 treatments (Table 5). This suggests that changes in the fruit composition were at least in
606 part due simply to increased concentrations of solids and solutes as a result of the reduced
607 water content. The relationship between acidity and waterlogging treatment was not
608 significant (the correlation between fruit water content and brix was described by y=-

609 1.239x+122.2, R^2=0.8258***; the correlation between fruit water content and acid was
610 described by y=-0.018+2.462, R^2=0.0078 ns). Therefore, the increased sugar/acid ratios
611 in the fruits may be due to the increased or concentrated sugar in the fruits. Generally,
612 tomato fruit quality is highly responsive to fluctuations in soil water (Zushi and Matsuzoe,
613 1998), and sweeter fruits can be produced using conditions of deficit irrigation (Lu et al.,
614 2021). In contrast to dry conditions, the condition was 'wet' in this study, however, the
615 water uptake by the root was restricted by the waterlogging treatment.

616 Processing tomato fruits have more carotenoids, such as lycopene, than table tomato
617 fruits (Sass-Kiss et al., 2005) because they are harvested when completely mature. In this
618 study, the overall contents of lycopene and β-carotene showed no significant changes
619 after the waterlogging treatments (Table 5). This result was in line with that for acidity
620 and differed from the results for the sugar/acid ratios (Table 5). Interestingly, however,
621 we did find interactions between treatment and cultivar in their effects on each carotenoid
622 (Table 5). Waterlogging increased the lycopene content in 'Lycoball' (Fig. 5A) and
623 increased the β-carotene contents in 'Natsunoshun' (Fig. 5B). A previous study of table
624 tomato showed that hypoxia in the root zone at the flowering stage caused a decrease in
625 the lycopene content of the fruits (Horchani et al., 2010). Thus, our results for 'Lycoball'
626 were in complete contrast to the results from the previous study. The accumulation of
627 carotenoids in tomato fruits is affected by not only the irrigation conditions but also by
628 other environmental factors such as illuminance, ambient temperature, and fertilization
629 (Dumas et al., 2003; Taber et al., 2008). These results suggested that the variable factors
630 of the changes in carotenoid levels appeared to be a specific response to waterlogging
631 treatment depending upon cultivars rather than these environmental conditions. Our

results indicated that the waterlogging conditions affected not only the fruit number and size of the processing tomatoes, but also aspects of fruit quality.

5. Conclusion

Although it was not clarified in our previous study (Jitsuyama et al., 2019), this trial shed light on the mechanisms that result in wet injury of processing tomatoes after waterlogging. At the onset of the waterlogging treatment, reduced soil nutrient levels and hypoxia cause reductions in nutrient uptake by the roots, leading to lower fruiting ratios and reductions in fruit numbers. If the waterlogging situation continues, the root biomass will be reduced, leading to further limitations in the uptake of nutrients and water, resulting in lower photosynthetic ability, and finally, drastic reduction of fruit size and total yields.

In regions where processing tomatoes are cultivated in converted paddy fields, such as central Hokkaido, excess moisture conditions for more than 5 days should be avoided by any means. This could be achieved by using engineering works such as FOEAS. However, if waterlogging cannot be avoided, the topdressing of fertilizer after the water has receded might be effective in mitigating the damage to yields, especially during hot summers. The choice of cultivar can also reduce the negative effects of waterlogging. ‘Natsunoshun’ is a high-yielding cultivar that produces fruit with a long shelf life. ‘Natsunoshun’ showed less root damage after waterlogging than the other two cultivars. Therefore, although its fruiting ratio is sensitive to waterlogging, ‘Natsunoshun’ has superior root characteristics for cultivation in converted paddy fields.

In this study, the cultivation conditions were quite different between the pot and field experiments, especially in the nutrition conditions and the spaces available for root growth. Nevertheless, each cultivar's responses to the excess moisture were similar between experiments, with significant correlations (data not shown). Therefore, pot experiments may be useful in preliminary surveys for selecting cultivars that can acclimate to waterlogging conditions. In the field, the planting density is higher and this may add further detrimental effects such as rebound of raindrops on the tomato fruits. Thus, further studies are needed to improve the production of processing tomatoes in converted paddy fields.

Acknowledgements

We would like to extend our appreciation to Mr. M. Torikoshi of the Hokkaido Research Organization, Agricultural Research Development, Ornamental Plants and Vegetables Research Center, and Mr. Y. Ohashi of the Hokkaido Research Organization, Agricultural Research Development, Central Agricultural Experimental Station for providing helpful suggestions. We would like to thank Ms. T. Chida of Sorachi Agricultural Extension Center and Mr. H. Sakamoto of Breeding Section, Nagano Vegetable and Ornamental Crops Agricultural Experiment Station for nursing seedlings and supplying seeds. We would also like to thank Mr. T. Tsunoda, Mr. S. Ichikawa and Mr. H. Nakano of the Field Science Center for the Northern Biosphere, Hokkaido University for assisting with the preparation of the experimental system and field.

837 Fig. 1 Plant growth conditions and fruit characters.

838 (A - C) Reddish mature fruits of 'Natsunoshun'(A), 'Suzukoma' (B) and 'Lycoball' (C). (D) In
839 the pot experiment, the 'WET' treatments were achieved using pots inserted in vinyl bags, as
840 illustrated by the upper photo and the lower diagram. (E) Damaged fruits, either undeveloped or
841 displaying blossom-end rot. Scale bars represent 1 cm. (F) Cultivation of 'Natsunoshun' in the
842 field experiment. (G) The WET10 waterlogging treatment in the field experiment.

843

844 Fig. 2. Interactions among variables affecting yield parameters in the pot experiment.

845 (A) Y x C interactions in their effects on yield. (B) Y x T x C interactions in their effects on yield.
846 (C) Y x T x C interactions in their effects on the number of fruits. Data represent means from 4
847 replications, and bars show standard errors. Different letters above the bars indicate significant
848 differences among treatments and growth stages at the 5% level (Tukey-Kramer test).

849

850 Fig. 3. Interactions among variables affecting fruiting ratios in the pot experiment.

851 (A) Y x C interactions in their effects on fruiting ratio (B) T x C interactions in their effects on
852 fruiting ratio. Data represent means from 4 replications, and bars show standard errors. Different
853 letters above the bars indicate significant differences among treatments and growth stages at the
854 5% level (Tukey-Kramer test).

855

856 Fig. 4. A-D. Interactions among variables affecting root dry weight and the fruit delivery ratio
857 (FDR) in the pot experiment.

858 (A) Y x T interactions in their effects on root dry weight. (B) Y x T interactions in their effects
859 on leaf area. (C) Y x C interactions in their effects on FDR. (D) T x C interactions in their effects
860 on root dry weight.
861 Data represent means from 4 replications, and bars show standard errors. Different letters above
862 the bars indicate significant differences among treatments and growth stages at the 5% level
863 (Tukey-Kramer test).
864
865 Fig. 5. Interactions among variables affecting the fruit lycopene and β-carotene contents in the
866 pot experiment.
867 (A) T x C interactions in their effects on the lycopene content. (B) T x C interactions in their
868 effects on the β-carotene content.
869 Data represent means from 5 replications, and bars show standard errors. Different letters above
870 the bars indicate significant differences among treatments and growth stages at the 5% level
871 (Tukey-Kramer test).
872
873 Fig. 6. Interactions among variables affecting the blossom-end rot ratio and the immature fruit
874 ratio in the field experiment.
875 (A) T x C interactions in their effects on the blossom-end rot ratio. (B) T x C interactions in their
876 effects on the immature fruit ratio.
877 Data represent means from 5 replications, and bars show standard errors. Different letters above
878 the bars indicate significant differences among treatments and growth stages at the 5% level
879 (Tukey-Kramer test).
880

881 Fig. S1. Relationships between the average fruit weight and yield (●) and between the fruit
882 number per plant and the yield (○) in the pot experiment.
883 (A) 'Natsunoshun'. (B) 'Lycoball'. (C) and 'Suzukoma'.
884 Each value represents the average of two years. The asterisks ***, **, and * represent significance
885 in the regression analysis at the 0.1%, 1%, and 5% levels using Pearson's correlation coefficient.
886
887 Fig. S2. Relationships between the average fruit weight and yield (●) and between the fruit
888 number per plant and the yield (○) in the field experiment.
889 (A) 'Natsunoshun'. (B) 'Lycoball' (C) 'Suzukoma'.
890 The asterisks ***, **, and * represent significance in the regression analysis at the 0.1%, 1%, and
891 5% levels using Pearson's correlation coefficient.
892
893 Fig. S3. Plants grown in the field and pot experiments.
894 (A) A 'Natsunoshun' plant before the waterlogging treatment in the field. (B) A wilted
895 'Natsunoshun' plant at day 5 of the WET10 treatment in the field. (C) The base of a 'Natsunoshun'
896 plant from the CONT treatment at the flowering stage in the pot experiment. D: The base of a
897 'Natsunoshun' plant from the WET3 treatment in the pot experiment. Adventitious roots are
898 shown at the base of the stem. Scale bars represent 1 cm.

	WET10	1396.7 (20.6)		34.8 (0.4)		0.78 (0.02)		823.0 (133.4)	

Each value indicates the mean (± S.E.) (n=3), and different letters in each column represent significant differences at the 5% level (Tukey-Kramer's test). P: available phosphoric acid, K: exchangeable potassium, Mg: exchangeable magnesium, Ca: exchangeable calcium, Cu: soluble copper, Zn: soluble zinc, Mn: easy reducible manganese, B: hot water soluble boron, N: nitrogen. The α-glucosidase activity represents microbial activity.

Bold values: Higher than the reference value.

Italic values: Lower than the reference value (Tokachi Agricultural Cooperative Association).
