Effects of basalt application on soil physical properties and CO₂ dynamics in agricultural soils

（玄武岩施用が農地土壌の土壌物理性およびCO₂動態に及ぼす影響）

Enhanced rock weathering (ERW) using finely crushed silicates such as basalt has gained attention for its potential to transform atmospheric CO₂ to bicarbonate through mineral dissolution while improving soil fertility. However, existing studies have focused mainly on geochemical effects, such as pH shifts, dissolution rates, and inorganic carbon formation, whereas the impacts on soil physical properties, coupled water–gas transport, and CO₂ production remain insufficiently understood. This study investigated how basalt application alters soil physical properties, mass transport, and soil carbon dynamics in agricultural soils.

1. Effects of basalt application on soil CO₂ respiration: Incubation experiments

90-day incubation experiments in a Gray-lowland soil and a Red-yellow soil were conducted to quantify short-term basalt effects on CO₂ emission, DOC (dissolved organic carbon) fractions, and pH under constant soil moisture and 25 °C in open air. Both soils showed an initial CO₂ pulse that rapidly declined, with basalt increasing CO₂ emission at the early stage due to a transient rise in H₂O-extractable DOC. It is likely due to stimulated respiration and DOC release from exchangeable pool under elevated soil pH. And the increased exchangeable Mg in both soils indicates rock dissolution. Overall, basalt did not increase consistent CO₂ production, instead, pH-driven DOC desorption might produce short-term respiration peaks, with soil types determining the magnitude and duration of responses.

2. Effect of basalt application on soil physical properties and soil CO₂ dynamics: Field monitoring

A two-years field monitoring was carried out in a cultivated (soybean in 2023, maize in 2024) gray-lowland field (Hokkaido University) following the surface application of basalt (15 kg m⁻²). Soil CO₂, water content, temperature, and water potential were continuously measured at 10–40 cm. Basalt application increased bulk density and

reduced total porosity while enhancing water retention, but effects on saturated hydraulic conductivity and gas diffusivity were minimal. In 2023, basalt-amended plots exhibited higher CO₂ concentrations and fluxes, with cumulative CO₂ production at a given depth exceeding the control, likely suggesting pH-driven stimulation of microbial activity under wetter conditions. In 2024, treatment differences became smaller, consistent with the diminished pH contrast between treatments.

3. Reactive transport modeling of soil CO₂ dynamics under ERW

Reactive transport model against mass and heat transport considering CO₂ production and rock dissolution was developed. Scenario-based (compaction-only and compaction with weathering scenarios) simulations were conducted to isolate physical and geochemical effects of basalt application. In the compaction-only scenario, the increases in bulk density produced lower total and air-filled porosity, leading to consistent higher CO₂(g) peaks especially after rainfall but almost no change in cumulative CO₂ flux. In the compaction with weathering scenario, olivine dissolution increased pH by ~1 unit and elevated DIC (dissolved inorganic carbon) concentrations, whereas soil CO₂(g) generally decreased due to dissolution consumption. Cumulative DIC fluxes also slightly increased in the presence of olivine although gas diffusion and water percolation were limited due to enhanced water retention. Weathering effects were stronger in the clayey soil, where higher water residence enhanced CO₂ retention and dissolution. Overall, basalt-induced chemical changes highly dominated soil CO₂ profiles and dynamics.
